General for all vaccines, including diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP); pediatric diphtheria-tetanus toxoid (DT); adult tetanus-diphtheria toxoid (Td); inactivated poliovirus vaccine (IPV); measles-mumps-rubella vaccine (MMR); *Haemophilus influenzae* type b vaccine (Hib); hepatitis A vaccine; hepatitis B vaccine; varicella vaccine; pneumococcal conjugate vaccine (PCV); influenza vaccine; and pneumococcal polysaccharide vaccine (PPV)	**Contraindications** Serious allergic reaction (e.g., anaphylaxis) after a previous vaccine dose Serious allergic reaction (e.g., anaphylaxis) to a vaccine component	Mild acute illness with or without fever Mild to moderate local reaction (i.e., swelling, redness, soreness); low-grade or moderate fever after previous dose Lack of previous physical examination in well-appearing person
	Precautions Moderate or severe acute illness with or without fever	Current antimicrobial therapy Convalescent phase of illness Premature birth (hepatitis B vaccine is an exception in certain circumstances)[‡] Recent exposure to an infections disease History of penicillin allergy, other nonvaccine allergies, relatives with allergies, receiving allergen extract immunotherapy

DTaP	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component Encephalopathy (e.g., coma, decreased level of consciousness; prolonged seizures) within 7 days of administration of previous dose of DTP or DTaP Progressive neurologic disorder, including infantile spasms, uncontrolled epilepsy, progressive encephalopathy: defer DTaP until neurologic status clarified and stabilized.	Temperature of <40.5℃, fussiness or mild drowsiness after a previous dose of diphtheria toxoid-tetanus toxoid-perfussis vaccine (DTP)/DTaP Family history of seizures[§] Family history of sudden infant death syndrome Family history of an adverse event after DTP or DTaP administration Stable neurologic conditions (e.g., cerebral palsy, well-controlled convulsions, developmental delay)
	Precautions Fever of >40.5℃ =48 hours after vaccination with a previous dose of DTP or DTaP Collapse or shock-like state (i.e., hypotonic hyporesponsive episode) =48 hours after receiving a previous dose of DTP/DTaP Seizure =3 days of receiving a previous dose of DTP/DTaP[§] Persistent, inconsolable crying lasting =3 and hours and =48 hours after receiving a previous dose of DTP/DTaP Moderate or severe lasting =3 and hours and =48 hours after receiving a previous dose of DTP/DTaP Moderate or severe acute illness with or without fever	
DT, Td	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component	
	Precautions Guillain-Barré syndrome =6 weeks after previous dose of tetanus toxoid-containing vaccine Moderate or severe acute illness with or without fever	
IPV	**Contraindications** Severe allergic reaction to previous dose or vaccine component	—
	Precautions Pregnancy Moderate or severe acute illness with or without fever	

MMR[¶]	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component Pregnancy Known severe immunodeficiency (e.g., hematologic and solid tumors; congenital immunodeficiency; long-term immunosuppressive therapy,[€] or severely symptomatic human immunodeficiency virus [HIV] infection)	Positive tuberculin skin test Simultaneous TB skin testing[‡] Breast-feeding Pregnancy of recipient's mother or other close or household contact Recipient is child-bearing–age female Immunodeficient family member or household contact Asymptomatic or mildly symptomatic HIV infection
	Precautions Recent (=11 months) receipt of antibody-containing blood product (specific interval depends on product)[£] History of thrombocytopenia or thrombocytopenic purpura Moderate or severe acute illness with or without fever	Allergy to eggs
Hib	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component Age <6 weeks	—
	Precaution Moderate or severe acute illness with or without fever	
Hepatitis B	**Contraindication** Severe allergic reaction after a previous dose or to a vaccine component	Pregnancy Autoimmune disease (e.g., systemic lupus erythematosis or rheumatoid arthritis)
	Precautions Infant weighing <2,000 grams[†] Moderate or severe acute illness with or without fever	
Hepatitis A	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component	—
	Precautions Pregnancy Moderate or severe acute illness with or without fever	
Varicella[¶]	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component Substantial supression of cellular immunity Pregnancy	Pregnancy of recipient's mother or other close or household contact Immunodeficient family member or household contact Asymptomatic or mildly symptomatic HIV infection Humoral immunodeficiency (e.g., agammaglobulinemia)
	Precautions Recent (=11 months) receipt of antibody-containing blood product (specific interval depends on product)[£] Moderate or severe acute illness with or without fever	

PCV	**Contraindication** Severe allergic reaction after a previous dose or to a vaccine component	—
	Precaution Moderate or severe acute illness with or without fever	
Influenza	**Contraindication** Severe allergic reaction to previous dose or vaccine component, including egg protein	Nonsevere (e.g., contact) allergy to latex or thimeros Concurrent administration of coumadin or aminophyl line
	Precautions Moderate or severe acute illness with or without fever	
PPV	**Contraindication** Severe allergic reaction after a previous dose or to a vaccine component	—
	Precaution Moderate or severe acute illness with or without fever	

If a vaccinee experiences a presumed vaccine-related rash 7–25 days after vaccination, avoid direct contact with immunocompromised persons for the duration of the rash.

From Centers for Disease Control and Prevention: General recommendations on immunization: Recommendations of the Advisory Committee on Immunization Practices (ACIP) and the American Academy of Family Physicians (AAFP). MMWR 2002; 51 (RR-2):1–35.

** Events or conditions listed as precautions should be reviewed carefully. Benefits and risks of administering a specific vaccine to a person under these circumstances should be considered. If the risk from the vaccine is believed to outweight the benefit, the vaccine should not be administered. If the benefit of vaccination is believed to outweigh the risk, the vaccine should be administered. Whether and when to administer DTaP to children with proven or suspected underlying neurologic disorders should be decided on a case-by-case basis.*

†Hepatitis B vaccination should be deferred for infants weighing <2,000 grams if the mother is documented to be hepatitis B surface antigen (HBsAg)-negative at the time of the infant's birth. Vaccination can commence at chronological age 1 month. For infants born to HBsAg-positive women, hepatitis B immunoglobulin and hepatitis B vaccine should be administered at or soon after birth regardless of weight. See text for details.

§Acetaminophen or other appropriate antipyretic can be administered to children with a personal or family history of seizures at the time of DTaP vaccination and every 4–6 hours for 24 hours thereafter to reduce the possibility of postvaccination fever (Source: American Academy of Pediatrics. Active immunization. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2000).

¶MMR and varicella vaccines can be administered on the same day. If not administered on the same day, these vaccines should be separated by =28 days.

¢ Substantially immunosuppressive steroid dose is considered to be =2 wk of daily receipt of 20?mg or 2?mg/kg body weight of prednisone or equivalent.

‡ Measles vaccination can suppress tuberculin reactivity temporarily. Measles-containing vaccine can be administered on the same day as tuberculin skin testing. If testing cannot be performed until after the day of MMR vaccination, the test should be postponed for =4 wk after the vaccination. If an urgent need exists to perform skin test, do so with the understanding that reactivity might be reduced by the vaccine.

£ See text for details.

eggs or chicken embryo fibroblast tissue culture, include those for measles, mumps, influenza, and yellow fever. Measles and mumps vaccines, however, contain insignificant amounts of egg proteins, and persons with hypersensitivity to eggs are at negligible risk of anaphylactic reactions from these vaccines. As a result, skin testing with measles vaccine is not predictive of a subsequent allergic reaction to vaccination. Hypersensitivity reactions to MMR that were previously attributed to egg protein may have been caused by allergic reactions to the gelatin stabilizer in the vaccine.

A generic precaution is moderate or severe acute illness, regardless of the presence or absence of fever. A mild illness does not impair the immunogenicity and safety of vaccines. Failure to vaccinate children with minor, acute illness is a missed opportunity and can seriously impede immunization delivery.

Administration of live-virus vaccines (e.g., MMR, OPV, and varicella) generally is contraindicated in immunocompromised persons, including recipients of high-dose corticosteroids. The exception is measles vaccine, which is recommended for HIV-infected persons who are not severely immunosuppressed (see Chapter 254).

Because of the theoretical risk to a developing fetus, live-virus vaccines in most cases are not recommended during pregnancy. However, inadvertent vaccination is not necessarily a reason for

termination of pregnancy and some live-virus vaccines (e.g., OPV, influenza, and yellow fever) can be given to pregnant women. Influenza vaccine is specifically recommended for all pregnant women who will be in the 2nd or 3rd trimester (=14 wk gestation) during the influenza season (late November through March) because of the increased morbidity of influenza in pregnant women.

In some recipients, vaccines can cause severe reactions that may constitute contraindications or precautions to subsequent administration of the specific vaccine. An example is the contraindication to further doses of DTP or DTaP if

encephalopathy occurs within 7 days of administration of a previous dose of either DTP or DTaP. In contrast, a history of a temperature of 40.5°C or greater (=105°F) within 48?hr of a prior dose is a precaution. In most cases in this circumstance, further doses of DTaP or DTP would not be given. However, if an epidemic of pertussis were occurring in the community, the potential benefit to the child of completing the immunization series may be greater than the risk of recurrence of a severe febrile reaction attributed to pertussis vaccine, the consequences of which are unknown.

VACCINES IN SPECIAL CIRCUMSTANCES

Indications for vaccination also involve considerations of the immunologic status of a child and exposure to infection. As a result, in special circumstances, immunization recommendations may be different from those for most other children.

Immunodeficiency.

Recommendations for vaccination of immunocompromised persons vary according to the degree and cause of the immunodeficiency, risk of exposure to the disease, and the type of vaccine (Table 282–4). Specific recommendations for HIV-infected children are given in Figure 254–2 . Live-bacteria (e.g., oral typhoid) and live-virus vaccines (e.g., MMR, varicella, and rotavirus) are contraindicated in most circumstances involving clinically significant immunosuppression. An exception is

TABLE 282-4 -- **Recommendations for Immunization of Immunocompron**

Adapted from Centers for Disease Control and Prevention: Recommendations of the Advisory Cor of vaccines and immune globulino in persons with altered immunocompetence. MMWR *Morbid Mc*

**Severe immunosuppression can be the result of congenital immunodeficiency, HIV infection, leukemia, lymphoma, aplastic anemia, generalized malignancy or therapy with alkylating agents, antimetabolites, radiation, or large amounts of corticosteroids.*

†Live vaccines are contraindicated in solid organ transplant recipients and with chronic immunosuppressive therapy.

‡MMR vaccination is recommended for all ***asymptomatic*** *HIV-infected persons who do not have evidence of severe immunosuppression for whom measles vaccination would otherwise be indicated. MMR vaccination should be considered for all* ***symptomatic*** *HIV-infected persons who do not have evidence of severe immunosuppression or of measles immunity (see Chapter 254).*

§Two doses of varicella vaccine, administered 3 mo apart, should be considered for asymptomatic or mildly symptomatic HIV-infected children in CDC class N1 or A1 with age-specific T-cell percentages of =25%

Varicella vaccine is not licensed for use in persons who have any malignant condition, including blood dyscrasias, eukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems. Varicella vaccine should not be administered to persons who have cellular immunodeficiencies, but persons with impaired humoral immunity may be vaccinated. An investigational protocol exists for use of varicella vaccine in patients with acute lymphoblastic leukemia. Varicella vaccine should not be administered to persons who have a family history of congenital or hereditary immunodeficiency in first-degree relatives unless the immune competence of the potential vaccine recipient has been clinically substantiated or verified by a laboratory. Varicella vaccine should not be administered to persons receiving immunosuppressive therapy (except children who have ALL in remission, as noted above), including systemic corticosteroids, =2?mg/kg or 20?mg/day of prednisone or its equivalent.

¶Children who have completed the PCV7 vaccination series before age 2 yr and who are among risk groups for which PPV23 is already recommended should receive one dose of PPV23 at age 2 yr (=2 mo after the last dose of PCV7).These groups at high risk include children with sickle cell disease, functional or anatomic asplenia, HIV infection, and immunocompromising or chronic diseases.

¢Yellow fever vaccine should be considered for patients when exposure to yellow fever cannot be avoided.

MMR and varicella vaccination of HIV-infected children who are not severely immunosuppressed (see Chapter 254). Children and adolescents with acute lymphocytic leukemia in remission can receive varicella vaccine under an investigational protocol provided appropriate institutional review board approval and informed consent have been obtained. The vaccine in this circumstance is available without cost from the manufacturer. OPV is contraindicated in households with immunocompromised persons because of a risk of vaccine-associated paralytic poliomyelitis.

Influenza and pneumococcal vaccines are indicated at the appropriate ages for household contacts of immunocompromised persons to help prevent spread of infection among these high-risk patients. Although bacillus of Calmette-Guérin vaccine (BCG) is contraindicated in HIV-infected children in the United States, the World Health Organization (WHO) recommends giving BCG to asymptomatic HIV-infected children in areas with a high incidence of tuberculosis.

Live-virus vaccines should be administered with caution to children receiving corticosteroids. Children receiving physiologic or low doses of corticosteroids, defined as less than 2?mg/ kg/24?hr of prednisone or its equivalent, or less than 20?mg/24?hr if they weigh more than 10?kg, can be immunized while on treatment. Children receiving 2?mg/kg/24?hr or more of daily, alternate-day prednisone or its equivalent, or 20?mg or more daily if they weigh more than 10?kg, for fewer than 14 days should have live-virus immunizations deferred until at least discontinuation of corticosteroids. If the duration is 14 days or more, immunization should be deferred for at least 1 month.

PRETERM INFANTS.

The immune response to vaccination is a function of postnatal rather than gestational age. Prematurity does not increase the incidence of vaccine-related adverse events. Hence, preterm infants, including those of very low birthweight, should be vaccinated at the same chronologic age as full-term infants and according to the routine childhood immunization schedule (see Fig. 282–1). One exception to this recommendation is hepatitis B vaccination of those born of HBsAg-negative mothers with low birthweights (i.e., <2?kg). Initiation of vaccination in this case should be delayed until the infant is 1 mo of age. Vaccine in conjunction with hepatitis B immunoglobulin (HBIG) should be given to low birthweight infants born of HBs-positive mothers at birth but the vaccine dose is not counted in the completion of a three-dose primary hepatitis B vaccine schedule. The dose for preterm infants should not be reduced for any vaccine.

Breast-Feeding.

Human milk does not adversely affect the immune response of infants and breast-feeding is not a contraindication to any vaccine, including OPV. Most live-virus vaccines, although they replicate in the mother, are not excreted in human milk. Breast-feeding women also may safely receive vaccines without interrupting breast-feeding, and their infants should be vaccinated according to routinely recommended vaccines.

Internationally Adopted Children.

Determination of whether a child has been adequately vaccinated on the basis of their country of origin and records alone is limited. Adopted children should receive vaccines according to the recommended schedules for children in the United States. Only written documentation should be accepted as evidence of prior vaccination. These records are more likely to predict protection if the vaccines, dates of administration, intervals between doses, and the child's age at the time of administrations are comparable to current recommendations in the United States. The majority of vaccines used worldwide are produced with adequate quality controls and standards and are potent.

Given the limitations in determining whether a child's prior vaccination history is reliable, one of several approaches can be followed. An acceptable one is repeating the vaccinations. Doing so is usually safe and avoids the need to obtain and interpret serologic antibody tests. If avoiding unnecessary injections is desired, judicious use of serologic testing may be helpful in determining which immunizations are needed.

POSTEXPOSURE IMMUNOPROPHYLAXIS

For certain infections, active or passive immunization shortly after exposure can prevent or ameliorate disease. For example, postexposure active immunization with rabies vaccine combined with passive immunization with rabies immune globulin (RIG) is highly effective in preventing rabies (see Chapter 251). Varicella-zoster immune globulin (VZIG) is indicated after susceptible persons who are immunocompromised are exposed to varicella (see Chapter 232). VZIG also is recommended for a newborn infant whose mother had onset of chickenpox within 5 days before to 2 days after delivery (see Chapter 232). For otherwise healthy, susceptible children exposed to varicella, administration of varicella vaccine within 72?hr of exposure is recommended to prevent or significantly modify disease (see Chapter 232). After a susceptible person is exposed to measles, either measles vaccine given within 72?hr or immune globulin given within 6 days can prevent or modify disease (see Chapter 225). Other infections for which passive immunization of a susceptible person is indicated after exposure are tetanus in wound management (see Chapter 194) and hepatitis A and hepatitis B (see Chapter 339).

PASSIVE IMMUNIZATION

Administration of an immune globulin is indicated in some circumstances for preventing specific infections. The different preparations include intramuscular immune globulin (IG), intravenous immune globulin (IVIG), and immune globulin preparations (termed *hyperimmune globulin*) that have high concentrations of specific antibody against a particular pathogen. These products, which historically were prepared from animal sera but today are derived from human sera, include VZIG, RIG, hepatitis B immune globulin (HBIG), cytomegalovirus immune globulin,

and respiratory syncytial virus (RSV) immune globulin for intravenous administration (RSV-IGIV).

A monoclonal antibody against RSV, palivizumab, administered intramuscularly at monthly intervals during the RSV season, also is available. Either palivizumab or RSV-IGIV is recommended for protecting high-risk children against serious complications of RSV disease (see Chapter 239). Other monoclonal antibody products may supplant hyperimmune globulins in the future.

Prevention of hepatitis A during foreign travel is another indication for passive immunization with IG. For children age 2 yr of age and older, however, active immunization with hepatitis A vaccine is preferred because the protection is prolonged, if not lifelong, in contrast to the temporary protection afforded by passive immunoprophylaxis.

ADVERSE EVENTS

Record Keeping and Reporting.

Accurate record keeping by physicians is required. Parents also should keep up-to-date immunization records for their children. In the United States, the **National Childhood Vaccine Injury Act** requires for childhood-mandated vaccines (i.e., those routinely recommended for all children) that health care providers record in a child's medical record the date of administration of the vaccine, manufacturer, lot number, and the name of the health care provider administering the vaccines.

All children and their parents or guardians should be informed about the benefits and risks of vaccines to be administered and the provisions of the National Vaccine Injury Compensation Program. The discussion should be in language understood by the recipient or parent or guardian, and ample

opportunity for questions and discussion should be provided. A **Vaccine Information Statement** for each vaccine has been prepared for this purpose by the Department of Health and Human Services; its use is required before each dose of vaccine.

Under the National Childhood Vaccine Injury Act, all temporally associated events severe enough for a patient to seek medical attention should be reported to the **Vaccine Adverse Events Reporting System (VAERS)**. In addition, specific adverse events occurring in recipients of childhood-mandated vaccines are required to be reported. Forms, instructions on reporting, and additional information can be obtained from the **National Vaccine Injury Compensation Program** (800-338-2382 and http://www.vaers.org/).

Compensation for Vaccine Injuries.

The Vaccine Injury Compensation Program (VICP) is a no-fault federal program that ensures fairness to persons who have suffered certain vaccine-related injuries and protects federal, state, and local immunization programs, private immunization providers, and vaccine manufacturers. The program is designed to provide prompt and fair compensation to the families of children who have died or have been injured as a result of routinely required immunization and to reduce the adverse impact of the tort judicial system on vaccine supply, cost, innovation, and development. This program provides no-fault compensation for specific adverse events associated with vaccines. These events can be accessed at the VICP Internet site (http://www.vaers.org).

DELIVERY OF VACCINES

Success of vaccination in preventing childhood infectious diseases necessitates effective means of vaccine delivery so that children receive recommended immunizations on schedule. In the United States, high rates of immunization in school-aged children have been achieved for the past 2 decades, in part because of state laws requiring immunization for school entry. In contrast to current rates of approximately 95% or higher in school-aged children, immunization rates in infants and young children in the 1980s were significantly lower; rates ranged from 18–79% for completed vaccinations by the 2nd birthday. This failure to immunize young children was a major factor in the 1989–1991 measles outbreaks in urban areas. Major barriers to successful infant and childhood immunization that were identified in these outbreaks include the following: inadequate access to immunization services, missed opportunities to administer vaccines, inadequate resources for public health and preventive programs, and low public awareness and resulting lack of public demand for immunization.

This recognition of low immunization rates prompted a national campaign to achieve the goal of 90% vaccine coverage of children by 2 yr of age. Initiatives included improved access to vaccines, education of health care providers, and the development of standards for pediatric immunization practices. These standards serve as guidelines for improving the delivery of vaccines and have recently been updated by the National Vaccine Advisory Committee of the Department of Health and Human Services (Box 282–1). They include readily available vaccination services, evaluation of immunization status of patients at all medical visits, effective communication with vaccine recipients about vaccine benefits and risks, use of valid contraindications, simultaneous administration of all indicated vaccines, and routine patient record reviews and assessments by providers of the immunization status of their patients. An important principle in these standards is the need to eliminate missed opportunities to vaccinate infants and children.

These and other initiatives have resulted in increasing immunization rates of young children in recent years. Since 1995, composite vaccination coverage rates for preschool-aged children have been approximately 75% or greater. According to the National Immunization Survey, coverage rates among children

Box 282-1. Standards for Child and Adolescent Immunization Practices

1. Vaccination services are readily available.
2. Vaccinations are coordinated with other health care services and provided in a medical home when possible.
3. Barriers to vaccination are identified and minimized.
4. Patient costs are minimized.
5. Health care professionals review the vaccination and health status of patients at every encounter to determine which vaccines are indicated.
6. Health care professionals assess for and follow only medically accepted contraindications.
7. Parents/guardians and patients are educated about the risks and benefits of vaccination in a culturally appropriate manner and in easy-to-understand language.
8. Health care professionals follow appropriate procedures for vaccine storage and handling.
9. Up-to-date, written vaccination protocols are accessible at all locations where vaccines are administered.
10. Persons who administer vaccines and staff who manage or support vaccine administration are knowledgeable and receive on-going education.
11. Health care professionals simultaneously administer as many indicated doses as possible.
12. Vaccination records for patients are accurate, complete, and easily accessible.
13. Health care professionals report adverse events following vaccination promptly and accurately to the Vaccine Adverse Event Reporting System (VAERS) and are aware of a separate program, the National Vaccine Injury Compensation Program (VICP).
14. All personnel who have contact

Event Reporting System (VAERS) and are aware of a separate program, the National Vaccine Injury Compensation Program (VICP).
14. All personnel who have contact
with patients are appropriately vaccinated.
15. Systems are used to remind parents/guardians, patients, and health care professionals when vaccines are due and to recall those who are overdue.
16. Office-or clinic-based patient record reviews and vaccination coverage assessments are performed annually.
17. Health care professionals practice community-based approaches.

19–35 mo of age in 2001 were 73.7% for completion of the schedule of four doses of DTaP/DTP/DT, three doses of poliovirus vaccines, three doses of Hib vaccine, three doses of hepatitis B vaccine, and one dose of measles-containing vaccine. All of the national coverage goals for specific vaccines established in the Childhood Immunization Initiative have been met, and vaccination rates are the highest ever recorded in the United States for preschool children. The rate for varicella vaccination rose from 67% in 2000 to 76% in 2001. This success reflects the collaborative efforts of the public and private sectors in public health.

INTERNATIONAL CONSIDERATIONS

Since the establishment of the Expanded Programme on Immunization (EPI) of the WHO, immunization rates for the basic children's vaccines increased from 5% to as high as approximately 80% worldwide. At least 2.7 million deaths due to measles, neonatal tetanus, and pertussis and 200,000 cases of paralysis due to poliomyelitis are prevented each year. Despite the successes of the EPI, which include elimination of poliomyelitis from the Americas, some vaccine-preventable diseases such as measles, pertussis, and neonatal tetanus remain prevalent in the developing world.

Vaccines against seven diseases are currently recommended by the EPI for routine use in the developing world and are BCG, DTP, OPV, measles, and hepatitis B vaccines for children and tetanus toxoid for pregnant women. Hib, Yellow fever, Japanese encephalitis, group A meningococcus, mumps, and rubella vaccines are used regionally, depending on the disease epidemiology and resources. Poliomyelitis has been targeted for global eradication by 2003.

Because infectious diseases know no geographic or political boundaries, uncontrolled disease anywhere in the world poses

a threat to the United States. Vaccines offer the opportunity to control and even eradicate some diseases. Successful eradication means that vaccines are no longer needed. The experience with smallpox demonstrates that the eradication of disease

is a remarkably sound economic investment. The total sum spent by the United States for the global smallpox eradication campaign has been recouped in 1968 dollars every 2.5 months since 1971. A similar achievement with poliomyelitis would save the United States more than $300 million each year in vaccine and associated delivery costs. **REFERENCES**

Chapter 283 - Infection Control and Prophylaxis

Margaret C. Fisher

Infection control is a vital part of pediatric medicine. Controlling infections requires an intact and active public health system, universal immunizations, optimal nutrition, and use of specific methods to prevent transmission of infection from child to child, child to adult, and adult to child. Infection control is the responsibility of every health care provider.

Nosocomial infections are those acquired during hospitalization. An estimated 3–5% of children admitted to hospitals acquire a nosocomial infection; rates are much higher in intensive care units. Infections are also acquired in emergency departments, physicians' offices, and long-term care settings. Medical devices are increasingly used in the home, and they also require appropriate infection control techniques. Education of home health care providers as well as of families is essential.

Determinants of infection include host factors, prior invasive procedures, use of catheters, use of antibiotics, and exposure to other patients, visitors, or health care providers with contagious diseases. Host factors that increase the risk for infection include anatomic abnormalities (e.g., dermoid sinuses, cleft palate, obstructive uropathy), damage to skin, organ dysfunction, malnutrition, and underlying diseases or co-morbidities. Diseases and therapies that alter immunity are most likely to predispose to infection. Prior procedures may introduce pathogens and damage anatomic host defenses. Intravenous and other catheters bypass host defenses, provide direct access to sterile sites, provide adherence sites for microbes, and may occlude normal ostia such as the eustachian tubes. Antibiotics often alter normal bowel flora and encourage colonization by resistant flora, and they may suppress hematopoiesis. Exposure to adults or children with contagious diseases is a clear risk for nosocomial transmission of disease.

Transmission of infectious agents occurs by various routes, but by far the most common and important route is via the hands. Children are constantly placing their own hands in their noses, eyes, and mouths; thus, child-to-child exchange of secretions is common whenever children are together. Bacteria, fungi, viruses, and parasites often travel on hands from one person to another. Medical equipment, toys, and hospital and office furnishings can be contaminated and thus have a role as fomites for transmission of potential pathogens. Thermometers and other

equipment that come into contact with mucous membranes are special risks. Some agents are disseminated by airborne transmission, such as varicella virus, measles virus, and *Mycobacterium tuberculosis*. Food and water can be contaminated and have been involved in hospital outbreaks.

Common causes of nosocomial infections in children are seasonal viruses, staphylococci, and gram-negative bacilli. Fungi and resistant bacteria are frequent causes of infection in immunocompromised children and in those who require intensive care and prolonged hospitalization. Common sites of infection are the respiratory tract, gastrointestinal tract, bloodstream, skin, and urinary tract.

Nosocomial infections cause considerable morbidity and occasional mortality; infections prolong hospital stays and increase health care costs. Surveillance for infection is the first step in identifying nosocomial infections and suggesting methods for prevention. Within hospitals, surveillance is the responsibility of the Infection Control Committee, a multidisciplinary group that collects and reviews surveillance data, establishes policy, and investigates outbreaks. Surveillance within outpatient settings and during home care is often less well established but no less important. Local, state, and federal health departments play important roles in identifying and controlling outbreaks and in establishing public health policy.

Prevention.

Prevention of infection is the goal.

HAND HYGIENE.

The most important measure in any infection control program is hand hygiene. Although much attention is directed at the types of soap used, the important component of handwashing is placement of the hands under water and use of friction with or without soap. Studies show that a 15-sec scrub removes the majority of transient flora but does not alter the permanent flora. A variety of hand gels and rubs can be used in place of handwashing. Waterless hand hygiene products have been shown to increase compliance and save time; these agents are now the preferred agents for routine hand hygiene. These products are effective in killing microbes; however, they will not remove dirt or debris. Hands should be cleaned before and after every patient encounter. Studies in child-care settings and schools have determined that handwashing can be taught to children and that the rates of infection are decreased when children as well as caregivers regularly clean their hands.

STANDARD PRECAUTIONS.

Standard precautions, formerly known as universal precautions, are intended to protect health care workers from blood and body fluids and should be used whenever providing care. Infected individuals are often contagious before symptoms of disease develop, and asymptomatic carriers are capable of transmitting the agent. Standard precautions involve the use of barriers—gloves, gowns, masks, goggles, and face shields—as needed to prevent transmission of microbes associated with contact with blood or body fluids.

ISOLATION.

Isolation of patients infected with certain pathogens decreases the risk of nosocomial transmission. The type of isolation depends on the infecting agent and the route of transmission. Contact transmission is the most frequent mode and involves direct contact or contact with a contaminated intermediate object. Droplet transmission is by droplets propelled a short distance through the air and deposited on mucous membranes. Airborne transmission occurs by dissemination of

droplet nuclei (=5?µm) of evaporated droplets or dust particles carrying the infectious agent.

Standard precautions are indicated for all patients and are appropriate in the office as well as the hospital. In addition, for hospitalized patients, transmission-based precautions are indicated for certain diseases (Table 283–1). Contact precautions include gowns and gloves and single room isolation. Droplet precautions include masks for close contact (<3?ft) and single room isolation. For both contact and droplet precautions, a single room is preferred but is not required. Cohorting of children infected with the same pathogen is acceptable. Airborne precautions include masks and single room isolation with negative-pressure ventilation. Transmission-based precautions are continued for as long as a patient is considered to be contagious.

The use of isolation techniques in an outpatient setting has not been studied. Each office must establish policies to ensure that the proper cleaning, disinfection, and sterilization methods are used. Many practices and clinics provide separate waiting areas for sick and well children. Triage of patients is essential to ensure that contagious children or adults are not present in waiting areas.

TABLE 283-1 -- **Selected Diseases and Indications for Transmission-Based Isolation in Addition to Standard Precautions**

Clinical Syndrome or Condition	Potential Pathogens	Empirical Precautions
Diarrhea		
Acute diarrhea with a likely infectious cause in an incontinent or diapered patient	*Salmonella, Shigella, Escherichia coli* O157:H7, rotavirus, hepatitis A	Contact
Diarrhea in any patient, especially an adult, with a history of recent antibiotic use	*Clostridum difficile*	Contact
Meningitis		

	*Neisseria meningitidis, Haemophilus influenzae*type b	Droplet
	Streptococcus pneumoniae	Standard
Rash or Exanthems		
Petechial/ecchymotic with fever	*N. meningitidis*	Droplet
Vesicular		
Chickenpox	Varicella-zoster virus	Airborne and contact
Zoster (localized in an immunocompetent patient)	Varicella-zoster virus	Standard
Zoster (disseminated or in an immunocompromised patient)	Varicella-zoster virus	Airborne and contact
Maculopapular with coryza and fever	Measles virus	Airborne
Erythema infectiosum	Parvovirus B19	Standard
Parvovirus B19 in an immunocompromised patient	Parvovirus B19	Droplet
Roseola	Human herpesvirus 6	Standard
Rubella	Rubella virus	Droplet
Respiratory Tract Infections		
Paroxysmal or severe persistent cough during periods of pertussis activity	*Bordetella pertussis*	Droplet
Bronchiolitis and croup, other lower respiratory tract infections in infants and young children	Respiratory syncytial or parainfluenza virus	Contact
Influenza	Influenza virus	Droplet
Atypical pneumonia	*Mycoplasma pneumoniae*	Droplet
Afebrile pneumonia in young infants	*Chlamydia trachomatis*	Standard
Diphtheria (pharyngeal)	*Corynebacterium diphtheriae*	Droplet
Pneumonic plague	*Yersinia pestis*	Droplet
Pneumococcal pneumonia	*Streptococcus pneumoniae*	Standard
Group A streptococcal pharyngitis, pneumonia, or scarlet fever in infants and young children	Group A streptococcus	Droplet
Skin Diseases		
Skin infections that are highly contagious or that may occur on dry skin (cutaneous diphtheria; herpes simplex virus, neonatal or mucocutaneous; impetigo; major or draining abscesses; cellulitis; decubiti; staphylococcal furunculosis; zoster disseminated or in an immunocompromised host)		Contact
Urinary Tract Infections		Standard
Other Infections		
Infection or colonization with multidrug-resistant organisms	Resistant bacteria	Contact
Invasive *Neisseria meningitidis*disease (meningitis, pneumonia, and sepsis)	*N. meningitidis*	Droplet
Invasive *Haemophilus influenzae* type b disease (meningitis, pneumonia, epiglottitis, and sepsis)	*H. influenzae* type b	Droplet
Viral infections spread by droplet transmission (adenovirus, influenza, mumps, parvovirus B19 in an immunocompromised patient, rubella)		Droplet

Adapted from Garner JS:The Hospital Infection Control Practices Advisory Committee: Guidelines for isolation precautions in hospitals. Infect Control Hosp Epidemiol 1996;17:53–80.

Outbreaks of measles in patients within the waiting area have been reported where airflow allowed the exhaust from the examination room to enter the waiting area. Cleaning the environment is important. Toys and items that are shared between patients should be cleaned between uses; soap and water are sufficient for these items. More complete disinfection or sterilization is required for items that encounter mucous membranes and for all reusable items used for body fluid sampling.

ADDITIONAL MEASURES.

Other preventive measures include aseptic technique, catheter care, prudent use of antibiotics, isolation of contagious patients, cleaning of the environment, disinfection and sterilization of medical equipment, reporting of infections, safe handling of needles and other sharp instruments, and establishment of employee health services. Aseptic technique must be used for all invasive procedures; this is especially important during catheter placement and manipulation. Catheter care also includes limiting the duration and number of catheters as much as possible and removing catheters as soon as they become unnecessary. Prudent use of antibiotics is important.

Surgical Prophylaxis.

Surgical prophylaxis is appropriate when there is a high risk of postoperative infection or when the consequences of infection are catastrophic. The choice of antibiotic depends on the site and type of surgery (Table 283–2). A useful classification of surgical procedures based on this risk recognizes four categories: clean wounds, clean contaminated wounds, contaminated wounds, and dirty and infected wounds. Clinical recommendations are standards of the American College of Surgeons, the Surgical Infection Society, and the American Academy of Pediatrics.

Clean wounds are uninfected operative wounds in which no inflammation is noted and the respiratory, alimentary, and genitourinary tracts and the oropharynx are not entered. In addition, the procedure is elective and is performed as primarily closed or drained with closed drainage. Operative incisional wounds after nonpenetrating trauma are included in this category. For clean wounds, prophylactic antimicrobial therapy is not recommended, except in patients at high risk for infection and in circumstances in which the consequences of infection are potentially life threatening (e.g., implantation of a prosthetic foreign body such as a prosthetic heart valve; open heart surgery for repair of structural defects; surgery in patients who are immunocompromised as a result of an inherited disease or are receiving corticosteroids or chemotherapy for malignancy; and newborn infants). Systemic antimicrobial agents have been recommended empirically for a clean procedure in patients with infection at another site.

Clean contaminated wounds are operative wounds in which the respiratory, alimentary, or genitourinary tract is entered under controlled conditions and does not have unusual contamination preoperatively. These wounds occur in operations that involve the biliary tract, appendix, vagina, and oropharynx and in which no evidence of infection or major break in technique is encountered, as well as in urgent or emergency surgery in an otherwise clean procedure. In clean but potentially contaminated procedures, the risk of contamination is variable. Recommendations for pediatric patients derived from data on adults suggest that prophylaxis be provided for procedures in patients with obstructive jaundice, certain alimentary tract procedures, and urinary tract surgery or instrumentation in the presence of bacteriuria or obstructive uropathy.

Contaminated wounds include open, fresh, and accidental wounds; major breaks in otherwise sterile operative technique; gross spillage from the gastrointestinal tract; penetrating trauma occurring less than 4?hr earlier; and incisions in which acute nonpurulent inflammation is encountered.

TABLE 283-2 -- **Common Surgical Procedures for Which Perioperative Prophylactic Antibiotics Are Recommended**

Surgical Procedure	Likely Pathogens	Suggested Drug
Clean Wounds		
Cardiac surgery (e.g., open heart surgery)	Skin flora, enteric gram-negative bacilli	Cefazolin or vancomycin
Vascular surgery		
Neurosurgery		
Orthopedic surgery (e.g., joint replacement)		
Clean Contaminated Wounds		
Head and neck surgery entering the oral cavity or pharynx	Skin flora, oral anaerobes, oral streptococci	Cefazolin or clindamycin
Gastrointestinal and genitourinary surgery	Enteric gram-negative bacilli, anaerobes, gram-positive cocci	Cefazolin; if colon involved, consider oral decontamination with neomycin and erythromycin
Contaminated Wounds		
Traumatic wounds (e.g., compound fracture)	Skin flora	Cefazolin
Dirty Wounds		
Appendectomy	Enteric gram-negative bacilli, anaerobes, gram-positive cocci	Cefoxitin, or clindamycin plus gentamicin
Colorectal surgery		

Dirty and infected wounds include penetrating traumatic wounds longer than 4?hr earlier, those with retained devitalized tissue, and those in which clinical infection is apparent or in which the viscera have been perforated. In contaminated and dirty or infected wound procedures, antimicrobial therapy is indicated and may need to be continued for 5–10 days.

In the truest sense, antimicrobial prophylaxis refers to the use of antibiotics before attachment of contaminating bacteria to the host tissues, as in the clean and potentially contaminated categories. Antibiotics given after the microbial attachment constitute therapy, as in the case of contaminated and dirty wounds.

When used, prophylactic antibiotics should be administered, preferably intravenously, approximately 30?min before the skin incision is made, with the intent of having peak concentrations of the drug at this time. Adequate plasma and tissue concentration of the drugs should be maintained until the incision is closed. Repeat doses are necessary only if the surgery lasts longer than 6?hr. Postoperative therapy is usually not necessary; in cases of contaminated surgery, antibiotics are continued as therapy for infection at the site. Drugs administered postoperatively for prophylaxis do not reduce the infection rate. For patients undergoing colonic procedures, additional oral antibiotics may be used and should also be given on the day before surgery.

The selection of antibiotic regimen for prophylaxis is based on the procedure, the expected contaminating organisms, and safety of the drugs. Because of the vast array of antibiotics available now, more than one regimen may be acceptable (see Table 283–2). Knowledge of the susceptibilities of the prevalent bacterial causes of nosocomial infections in each hospital is especially important in choosing drugs.

Employee Health.

Employee health is important because employees are at risk for acquiring infection from patients. This risk is minimized by use of standard precautions and hand hygiene before and after all patient contacts. Infected employees also pose a risk to patients. Within hospitals, personnel health services or departments of occupational safety and health manage employee health issues. New employees should be screened for the presence of infectious diseases. Their immunization history should be noted and necessary immunizations offered.

All health care workers (medical or nonmedical, paid or volunteer, full time or part time, student or nonstudent, with or without patient care responsibilities) who work in facilities that provide health care to patients (inpatient or outpatient, public or private) should be immune to measles, rubella, and varicella.

All employees who might be exposed to blood or body fluids should be immunized against hepatitis B. Annual influenza immunizations are recommended for all health care workers who have contact with patients at risk for influenza or its complications. This program lessens staff illness and absenteeism during the influenza season and reduces nosocomial infections. Immunizations should be encouraged and whenever possible should be provided free of charge. Each office and hospital must comply with the rules developed by the Occupational Safety and Health Administration. Furthermore, each office and hospital should have written policies about exclusion of infected staff. Regular educational sessions should be performed to ensure that the staff is aware of infection control methods and that they adhere to infection control policies. **REFERENCES**

Chapter 284 - Child Care and Communicable Diseases

Larry K. Pickering

An estimated 13 million children age 5 yr and younger and 60% of school-aged children younger than age 13 yr attend some form of child-care facility on a regular basis (see Chapter 32). Child-care facilities can be classified on the basis of size of enrollment, ages of attendees, health status of the children enrolled, and type of setting. As defined in the United States, child-care facilities consist of child-care centers, small and large family child-care homes, and facilities for ill children or children with special needs. Child-care centers are facilities where care and education are provided to any number of children in a nonresidential setting and the facility is open on a regular basis (i.e., not a drop-in facility). Centers are licensed and regulated by state governments and care for a larger number of children than are cared for in family homes. In contrast, family child-care homes are designated as small (1–6 children) or large (7–12 children), may be full day or part day, may expect regular daily attendance, or may be designed for sporadic use. Family homes generally are not licensed or registered, depending on state requirements.

Most studies of infectious diseases have been conducted in child-care centers among infant (birth–12 mo of age) and toddler (13–36 mo of age) groups. Almost any organism has the potential to be spread and cause disease in a child-care setting. Epidemiologic studies have established that children in child-care facilities are 2–18 times more likely to acquire certain infectious diseases than children not enrolled in child-care (Table 284–1). In addition, children in child-care facilities are at risk of receiving more courses of antimicrobial agents for longer periods and of acquiring antibiotic-resistant organisms. Transmission of organisms and illness in group care depends on the age and immune status of children involved, the season, hygiene practices, crowding, environmental characteristics of the facilities, and characteristics of particular organisms, including infectivity, survivability in the environment, and virulence. Rates of infection, duration of illness, and risk of hospitalization tend to decrease among children in child-care facilities after the first 6 mo of attendance and decline to levels observed among homebound children after 3 yr of age.

Epidemiology.

There are several different patterns of occurrence of infectious diseases among children in child care and their contacts. Respiratory tract infections and diarrhea are the most common diseases associated with child care. These infections occur in children, child-care staff, and household contacts and may spread into the community. Organisms such as enteric pathogens (see Chapter 321), which are transmitted by the fecal-oral route, and respiratory tract pathogens can infect both children and adults. Infections caused by hepatitis A virus may

TABLE 284-1 -- Infectious Diseases in the Child-Care Setting

Disease	Increased Incidence with Child Care
Respiratory Tract Infections	
Otitis media	Yes
Sinusitis	Probably
Pharyngitis	Probably
Pneumonia	Yes
Gastrointestinal Tract Infections	
Diarrhea (rotavirus, calicivirus, astrovirus, enteric adenovirus, *Giardia lamblia*, *Cryptosporidium*, *Shigella*, *Escherichia coli* O157:H7, and *Clostridium difficile*)	Yes
Hepatitis A	Yes
Skin Diseases	
Impetigo	Probably
Scabies	Probably
Pediculosis	Probably
Tinea (ringworm)	Probably
Invasive Bacteria Infections	
Haemophilus influenzae type b	No*
Neisseria meningitidis	Probably
Streptococcus pneumoniae	Yes
Aseptic Meningitis	
Enteroviruses	Probably
Herpesvirus Infections	

Cytomegalovirus	Yes
Varicella-zoster virus	Yes
Herpes simplex virus	Probably
Bloodborne Infections	
Hepatitis B	Few case reports
HIV	No cases reported
Hepatitis C	No cases reported
Vaccine-Preventable Diseases	
Measles, mumps, rubella, diphtheria, pertussis, tetanus	Not established
Polio	No
H. influenzae type b	No*
Varicella	Yes

** Not in the postvaccine era; yes in the prevaccine era.*

not be apparent in young children attending child care but may have a major clinical impact on older children and adult contacts, including child-care staff and household contacts. Other diseases, such as otitis media, varicella, and invasive *Haemophilus influenzae* type b disease, usually affect children rather than adults. Some infections, such as cytomegalovirus (CMV) and parvovirus B19, may have serious consequences for the fetuses of pregnant women or for certain immunosuppressed hosts. Bloodborne pathogens such as hepatitis B virus and HIV (see Chapter 254) can infect all ages but have rarely (hepatitis B) or never (HIV) been reported to be transmitted in a child-care setting. Skin infections and infestations are acquired through close personal contact and contaminated linens or clothing and more often affect children older than 2 yr of age.

RESPIRATORY TRACT INFECTIONS.

Respiratory tract infections account for the majority of child care–related illness. Children younger than 2 yr of age and who attend child-care centers have more upper and lower respiratory tract infections than age-matched children not in child care. The organisms responsible for illness are similar to those that circulate in the community and include respiratory syncytial virus, parainfluenza viruses, adenoviruses, rhinoviruses, coronaviruses, influenza viruses, parvovirus B19, *Streptococcus pneumoniae*, and, infrequently, *Bordetella pertussis* and *Mycobacterium tuberculosis.* The risk of developing otitis media is two to three times greater in children attending child-care centers than in children receiving home-based care. Otitis media is responsible for most of the antibiotic use in children younger than 3 yr of age in child care. These children also are at increased risk for recurrent otitis media, further increasing use of antimicrobial agents in this population. Although children in child care show earlier acquisition of pharyngeal carriage of group A *Streptococcus,* outbreaks of this organism are uncommon.

GASTROINTESTINAL TRACT INFECTIONS.

Acute infectious diarrhea is two to three times more common in children in child care than in children cared for in their homes. Outbreaks of diarrhea occur frequently in child-care centers and generally are caused by enteric viruses such as rotaviruses, enteric adenoviruses, astroviruses, and caliciviruses or by enteric parasites such as *Giardia lamblia* or *Cryptosporidium.* Low infective doses and high asymptomatic excretion rates characterize the more common enteropathogens, such as rotavirus and *G. lamblia.* Bacterial enteropathogens, such as *Shigella* and *Escherichia coli* O157:H7, and, less commonly, *Campylobacter, Clostridium difficile,* and *Bacillus cereus* (from contaminated fried rice) also have caused outbreaks of diarrhea in child-care settings. *Salmonella* rarely is associated with outbreaks of diarrhea in child-care settings. Hepatitis A in children enrolled in child-care facilities has resulted in community-wide outbreaks. Hepatitis A usually is mild or asymptomatic in young children and is identified when illness becomes manifested in older children or adults. Enteropathogens and hepatitis A virus are transmitted in child-care facilities by the fecal-oral route and rarely by contaminated food or water. Enteric illness and hepatitis A are more common in centers that care for children who are not toilet trained and where proper hygienic practices are lacking.

SKIN DISEASES.

The most commonly recognized skin infections or infestations in children in child care are impetigo caused by staphylococcus *aureus* or group A streptococcus, pediculosis, scabies, tinea capitis, and tinea corporis (ringworm). The magnitude of these infections and infestations in children in child care is not known. Parvovirus B19, which causes erythema infectiosum (fifth disease), is spread through the respiratory route, and outbreaks have occurred in child-care centers. As with CMV, the greatest health hazard is for pregnant women and immunocompromised hosts owing to their respective risks of fetal loss and aplastic crisis.

INVASIVE ORGANISMS.

Primary invasive disease caused by *H. influenzae* type b has been shown to be more common in children in child care; evidence for increased risk of subsequent or secondary disease from *H. influenzae* type b in a child-care setting is less convincing. Routine immunization against *H. influenzae* type b has reduced greatly the risk of primary invasive infection. There is an indication that the risk of primary disease caused by *Neisseria meningitidis* is higher among children in child care than among children cared for at home. Child-care attendance is associated with nasopharyngeal carriage of penicillin-resistant *Streptococcus pneumoniae* and invasive pneumococcal disease, especially among children with a history of recurrent

otitis media and antibiotic use. Secondary spread of *S. pneumoniae* and *N. meningitidis* has been reported, indicating the potential for outbreaks to occur in this setting. Use of *S. pneumoniae* conjugate vaccine will reduce the incidence of invasive disease and reduce carriage of serotypes of *S. pneumoniae* contained in the vaccine.

Outbreaks of aseptic meningitis from echovirus 30 have been reported among children in child-care centers, their parents, and their teachers.

HERPESVIRUSES.

Studies of CMV infection in child-care centers have shown that as many as 70% of diapered children continuously shed CMV in urine and saliva after acquisition. CMV-infected children often transmit the virus to other children with whom they have contact, as well as to 8–20% of their care providers and mothers per year. Transmission occurs as a result of contact with infected saliva or urine. Varicella frequently has been transmitted in child-care centers, but routine varicella immunization should reduce this risk. The role of child-care facilities in the spread of herpes simplex virus, especially during episodes of gingivostomatitis, requires further clarification.

BLOODBORNE ORGANISMS.

Hepatitis B virus (HBV), HIV, and hepatitis C virus (HCV) are bloodborne pathogens. Hepatitis B transmission among children in child care has been documented in a few instances, but the potential for transmission of this infection has declined with implementation of universal immunization of infants with HBV vaccine. Issues about HIV in child care include the potential risk of HIV transmission within the child-care setting and risks to HIV-infected children associated with acquisition of infectious agents. No cases of HIV transmission in out-of-home child care have been reported. Children with HIV infection enrolled in child-care facilities should be monitored for exposure to infectious diseases, and their health and immune status should be evaluated frequently. Transmission risks of HCV infection in child-care settings have not been reported.

ANTIBIOTIC USE AND BACTERIAL RESISTANCE.

Antibiotic resistance has become an alarming problem in child-care facilities because the frequency of infection by organisms resistant to frequently used antimicrobial agents has increased dramatically. The estimated annual rate of antibiotic use in children in child care is from two to four times higher than in age-matched children cared for at home. In addition, the mean duration of antibiotic treatment is four times longer in children in child care. This frequency of antibiotic use combined with the propensity for person-to-person transmission of pathogens in a crowded environment has resulted in an increased prevalence of antibiotic-resistant bacteria in the respiratory and intestinal tracts, including *S. pneumoniae, H. influenzae, Moraxella catarrhalis, E. coli* O157:H7, and *Shigella* species.

Prevention.

Written child-care center policies designed to prevent or control the spread of infectious agents should be available and reviewed regularly. Standards for environmental and personal hygiene should include maintenance of current immunization records for children and staff, appropriate exclusion policies, targeting frequently contaminated areas for environmental

cleaning, adherence to appropriate diaper changing procedures, appropriate handling of food, management of pets, and communicable disease surveillance and reporting. Educational strategies for improving adherence to these standards should be implemented. Appropriate and thorough hand hygiene is the most important factor for reducing infectious diseases in the child-care setting.

In the United States, there are 11 diseases and organisms for which all children should be immunized unless there are contraindications: diphtheria, pertussis, tetanus, measles, mumps, rubella, polio, hepatitis B, varicella, *H. influenzae* type b, and *S. pneumoniae*. Immunization against hepatitis A is routinely recommended for children 2 yr of age and older in high-risk groups and in certain geographic areas, including 11 western states. Immunization against influenza of children 6–23 mo of age is recommended, when feasible. High levels of immunization exist among children in licensed child-care facilities, in part because of laws in almost all states requiring age-appropriate immunizations of children attending licensed child-care programs and in part because of the increased rates of immunization of all children in the United States. The use of vaccines has had a significant beneficial effect on the health of children in child-care settings. Use of *H. influenzae* type b conjugate vaccines has practically eliminated disease associated with invasive *H. influenzae* type b organisms. HBV, varicella, conjugate pneumococcal vaccines, and hepatitis A vaccine in certain geographic locations should also benefit children in child-care centers. The role of influenza vaccine among children and adults in child-care settings requires further evaluation.

Child-care providers should receive all immunizations that are recommended routinely for adults. Local public health authorities should be notified about cases of communicable disease involving children or providers in child-care settings.

Standards.

Every state has specific standards for licensing and reviewing child-care centers and family child-care homes. The American Academy of Pediatrics and the American Public Health Association jointly publish comprehensive health and safety performance standards that can be used by pediatricians and other health care professionals to guide decisions about infectious diseases and other health care related matters in child-care facilities (available in print form and at http://nrc.uchsc.edu/).

Chapter 285 - Health Advice for Children Traveling Internationally

Chandy C. John
Robert A. Salata

The health risks and pre-travel requirements of children traveling internationally, particularly those who are younger than 2 years of age, differ from those of adults. Many physicians trained in developed countries are unfamiliar with the health hazards of international travel and with the frequently changing recommendations of measures to prevent illness during international travel. In the United States, recommendations and vaccine requirements for travel to different countries are provided in publications by the Centers for Disease Control and Prevention (CDC), including *Health Information for International Travel* (available from the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402-9235, and also at www.cdc.gov/travel/yb/index.htm).

General Travel Preparation.

Parents of traveling children should seek medical consultation at least 4–6 wk before departure to obtain a realistic assessment of health risks, a schedule of vaccinations and list of medications, and instructions on dealing with disease during travel.

HEALTH INSURANCE.

Parents should be encouraged to ask their insurers whether their health care plan covers health care internationally. If it does, parents should ask about the need for preauthorization for medical treatment, the level of co-payment required, and whether emergency medical evacuation is covered. Additional travel insurance that covers emergency medical evacuation and the costs of local care is available at reasonable rates through various providers, and parents should be made aware of this option.

UNDERLYING MEDICAL ILLNESS.

Parents of traveling children should be asked whether the child has any current health problems or has had any problems in the past that have required medical evaluation or medication. Children with medical conditions should take with them a brief medical summary. Parents should be counseled to take a sufficient supply of prescription medications for their children and to ensure that the bottles are clearly identified. For children requiring care by specialists, an international directory for that specialty can be consulted. A directory of physicians worldwide who speak English and who have met certain qualifications is available from the

International Association for Medical Assistance to Travelers (736 Center Street, Lewiston, NY 14092; telephone: 716-754-4883). If medical care is needed urgently when abroad, sources of information include the American embassy or consulate, hotel managers, travel agents catering to foreign tourists, and missionary hospitals. Children with chronic cardiopulmonary disease, diabetes, allergies, and gastrointestinal problems, especially diarrhea associated with malabsorption or inflammatory bowel disease, are at particular risk for health problems when traveling. Patients with insulin-dependent diabetes or hemophilia should carry an adequate supply of sterile needles, syringes, and disinfectant swabs. Special arrangements should be made for patients with bleeding disorders, those on anticoagulation therapy, and those who require hemodialysis. Biologic products such as clotting factor concentrates or immune globulin should be avoided if manufactured abroad. A travel health kit consisting of prescription medications and nonprescription items such as acetaminophen, an antihistamine, oral rehydration solution packets, antibiotic ointment, bandages, insect repellent, and sunscreen is highly recommended for all children.

SAFETY.

Injuries and motor vehicle accidents are the major causes of serious disability and loss of life during travel. The use of safety belts for children, preferably sitting in the rear seat, should be emphasized. When possible, child safety-restraint seats should be taken on the trip. Travelers to remote areas should be warned about the risks of contact with stray dogs (rabies), rodents (plague), and venomous animals (snake and scorpion bites can be fatal in infants). Swimming or diving in contaminated water can result in serious injury and can increase the risk of infections, including schistosomiasis, leptospirosis, and primary amebic meningoencephalitis. Many illnesses that develop in traveling children are related to risks that can be modified with proper advice and supervision by parents.

INFECTIOUS DISEASE PRECAUTIONS.

Infectious disease risks to traveling children can generally be divided into three categories: those that are foodborne, those that are transmitted by insects, and those from contact with an infected person or by needle or blood exposure.

Ingestion of contaminated food or water makes travel-associated diarrhea the most common health complaint among international travelers. Among the bacterial and protozoan infections children can acquire from contaminated water are shigellosis, salmonellosis, *Escherichia coli* infections, cholera, giardiasis, amebiasis, and cryptosporidiosis. Viral infections, particularly rotavirus infections, are also a major

cause of travel-associated diarrhea in children. Boiled water, hot beverages made with boiled water, and canned or bottled carbonated beverages are generally safest. Ice should be avoided, and tap water should not be used when brushing teeth. Boiling water for at least 1 minute is the most reliable method of water disinfection. An acceptable alternative is the use of a micropore filter with an on-demand iodine release system. Unpeeled fruit, uncooked vegetables, unpasteurized milk, milk products such as cheese, and undercooked meat or fish may all be contaminated and should be avoided. Fish, especially reef fish, red snapper, and barracuda, are of particular concern because they may possess toxins. Breast-feeding should be encouraged for young children, especially infants younger than 6 mo.

Insect-borne infections for which traveling children are at risk include malaria, yellow fever, dengue, Japanese encephalitis, filariasis, trypanosomiasis, and onchocerciasis, depending on the area of travel. Malaria, yellow fever, Japanese encephalitis, and filariasis are typically caused by night-biting mosquitoes, whereas dengue is usually caused by day-biting mosquitoes. Exposure to insect bites can be avoided by restricting high-risk activities, staying indoors in a screened and protected area from dusk to dawn, wearing appropriate attire, and using insect repellents containing permethrin or *N,N*-diethyl-M-toluamide (DEET). Rare instances of toxic encephalopathy have been reported in young children with exposure to high concentrations of DEET, but use of repellent with no more than 30% DEET and avoidance of repeated applications minimizes the risk of this complication. Bed nets, particularly permethrin-impregnated bed nets, also decrease the risk of insect bites.

Many of the infections that may be acquired by children traveling internationally through contact with other individuals are preventable by routine childhood immunizations. Other diseases transmitted through human contact include viral respiratory and gastrointestinal infections, hepatitis, and sexually transmitted diseases, including HIV infection. Many of these diseases are more prevalent in developing countries than in the United States. Adolescent travelers should be reminded that sexual encounters and needle or blood exposure (including tattooing and body piercing) carry a significant risk of HIV and hepatitis infection. Systematic screening of blood donations for HIV and other blood-borne infections is not yet feasible in many developing countries, so the safety of transfusion services in these countries cannot be ensured. Travelers may wish to have their blood typed before departure to determine whether family members or travel companions have similar blood types and might be able to donate blood for transfusion in an emergency situation.

Immunizations.

Parents should allow 4–6 wk before departure for optimal administration of vaccines to their children, because some immunizations require repeated doses for full protection and some vaccines and medications require either simultaneous or staggered dosing for optimal efficacy. The vaccines currently indicated for children traveling internationally, whether part of routine childhood immunization or travel-related, can be given concurrently with no decrease in safety or efficacy. Live-attenuated viral vaccines should be administered concurrently or at least 30 days apart to minimize interference. Intramuscular immune globulin (IG) interferes with the immune response to measles immunization and possibly to varicella immunization. If a child requires measles or varicella immunization, the vaccines should be given either 2 wk before or 3 mo after IG administration. IG does not interfere with the immune response to oral typhoid, oral poliovirus, or yellow fever vaccines.

Vaccine products produced in eggs (e.g., yellow fever, influenza) may contain an allergenic substance that causes hypersensitivity responses, including anaphylaxis in persons with known severe egg sensitivity. Screening by inquiring about adverse effects when eating eggs is a reasonable way to identify those at risk for anaphylaxis from receiving influenza or yellow fever vaccines. Although measles and mumps vaccines are produced in chick embryo cell cultures, children with egg allergy are at very low risk for anaphylaxis with these vaccines. Most hypersensitivity reactions to measles-containing vaccines have been attributed to trace amounts of gelatin or neomycin.

In general, live-virus vaccines (e.g., oral poliovirus, measles, varicella) and live bacterial vaccines (e.g., bacille Calmette-Guérin [BCG], oral typhoid) are contraindicated in immunocompromised persons (see Table 282–5). However, HIV-infected children who are not severely immunocompromised (see Chapter 254) should receive measles and varicella vaccines. Asymptomatic HIV-infected children may also be vaccinated against yellow fever if the risk is significant, but children with symptomatic HIV infection should not receive yellow fever vaccine. Inactivated vaccines and toxoids are not contraindicated in

immunocompromised children but may be associated with diminished immune responses.

ROUTINE CHILDHOOD VACCINATIONS.

All children who travel should be immunized according to the routine childhood immunization schedule with all vaccines appropriate for their age (see Chapter 282). The immunization schedule can be accelerated to maximize protection for traveling children, especially for unvaccinated or incompletely vaccinated children (see Table 282–1).

Diphtheria, Tetanus, and Pertussis.

Diphtheria is endemic in many developing countries. After the disintegration of the Soviet Union in 1991, diphtheria re-emerged in the new independent states. The highest incidence of diphtheria has been reported from Azerbaijan, Tajikistan, and Latvia. Tetanus is a major cause of worldwide neonatal mortality and is most prevalent in tropical countries. Neonatal tetanus usually occurs in infants born to inadequately vaccinated mothers in unhygienic conditions. Pertussis is common in developing countries and in some developed nations where pertussis immunization is less widespread than in the United States because of earlier concerns about pertussis vaccine side effects.

Protection is attained with four doses of DTaP, a booster at 4–6 yr of age, and subsequent tetanus boosters (with adult-type diphtheria and tetanus toxoids [dT])

every 10 yr (see Chapter 282). The schedule can be accelerated for children traveling internationally (Table 285–1). DT should be used for children younger than 7 yr of age and who have a contraindication to pertussis vaccine. Pertussis vaccination is not recommended for persons 7 yr of age or older.

Haemophilus influenzae type b.

Severe *H. influenzae* type b infection is most common in children 6 mo–1 yr of age, but one third of cases of invasive infection are found in children 18 mo of age or older. Before they travel, all unimmunized children younger than 60 mo and all children with chronic illness at risk for *H. influenzae* type b infections should be vaccinated (see Chapter 282).

Hepatitis B.

Hepatitis B is highly prevalent in eastern and southeastern Asia, sub-Saharan Africa, and the Pacific basin. In certain parts of the world, 8–15% of the population may be chronically infected. Situations in which disease transmission can occur include receipt of blood transfusions not screened for hepatitis B surface antigen, exposure to unsterilized needles, close contact with local children who have open skin lesions, and sexual exposure. Exposure to hepatitis B is more likely for

TABLE 285-1 -- **Accelerated Schedule of Routine Childhood Immunizations if Necessary for Travel**

Vaccine	Routine Schedule	Accelerated Schedule
Diphtheria, tetanus, pertussis	DTaP: 2, 4, 6, and 15–18 mo of age	DTaP: 6, 10, and 14 wk of age; 4th dose 6 mo after 3rd dose
	DTaP: 4–6 yr of age (booster)	DTaP: 4 yr of age (booster)
	dT every 10 yr	dT every 5 yr if at high risk
Haemophilus influenzae type b	HbOC or PRP-T: 2, 4, 6, and 12–15 mo of age	HbOC or PRP-T: 6, 10, and 14 wk and 12 mo of age
	PRP-OMP: 2, 4, and 12 mo of age	PRP-OMP: 6 and 10 wk and 12 mo of age
Hepatitis B	Birth, 1–2 mo and 6 mo of age	Birth, 1 and 2 mo of age; booster at 12 mo of age
Measles, mumps, rubella	MMR: 12–15 mo and 4–6 yr of age	MMR: Two doses at =12 mo of age, =4 wk apart
	Not routinely recommended for children <12 mo of age	May give first measles dose as early as 6 mo of age, with additional two doses age =12 mo, 4 wk apart
Poliomyelitis	IPV: 2, 4, and 6 mo of age; booster at 4–6 yr of age	IPV: 6, 10, and 14 wk of age; booster at 4–6 yr of age
	No additional boosters unless traveling to an endemic area	A single IPV lifetime booster for adolescents and adults who have completed primary immunization
Pneumococcus	Pneumococcal conjugate (PCV): 2, 4, 6, and 12–15 mo of age	PCV7: 6, 10, and 14 wk of age; 4th dose 2 mo after 3rd dose
Varicella	12–18 mo of age	12 mo (two doses 1 mo apart for persons =13 yr of age)

travelers residing for prolonged periods in endemic areas. Vaccination for hepatitis B is recommended for all children in the United States. The hepatitis B schedule can be accelerated (see Table 285–1). Partial protection may be provided by one or two doses.

Measles, Mumps, and Rubella.

Measles is still endemic in many developing countries and in some industrialized nations. Measles vaccine, preferably in combination with mumps and rubella vaccines (MMR), should be given to all children at 12–15 mo of age and at 4–6 yr of age, unless there is a contraindication (see Chapter 301). In children traveling internationally, the second vaccination can be given as soon as 4 wk after the first. In the accelerated schedule the first MMR vaccination can be given to children as early as 6 mo of age, but if the vaccine is given at earlier than 12 mo of age, two additional doses should be given at least 4 wk apart after 12 mo of age (see Table 285–1). Infants younger than 6 mo of age are protected by maternal antibodies. HIV-infected children who travel abroad should be vaccinated unless severely immunocompromised (see Table 254–2), because measles in HIV-infected children can be a devastating illness.

Pneumococcus.

Streptococcus pneumoniae is the leading cause of bacterial pneumonia and among the leading causes of bacteremia and bacterial meningitis in children in developing and industrialized nations. Immunization against *S. pneumoniae* with a protein-conjugated 7-valent pneumococcal vaccine is now part of routine childhood immunization in the United States. The four-dose schedule starts at 2 mo of age but can be accelerated for children preparing to travel (see Table 285–1). Unimmunized children older than 2 yr of age should be immunized only if they are at high risk, such as children with sickle cell disease, asplenia, HIV infection, congenital immunodeficiency, nephrotic syndrome, chronic cardiac or pulmonary disease, and those on immunosuppressive medication (see Chapter 282).

Poliomyelitis.

Poliomyelitis was eradicated from the Western hemisphere in 1991, but it remains endemic in several developing countries. The poliovirus vaccination schedule in the

United States is now a four-dose, all inactivated poliovirus (IPV) regimen (see Chapter 282). Immunization can be started as early as 4–6 wk of age (see Table 285–1). In the United States, oral poliovirus vaccine (OPV) is now recommended only for children who will be traveling in less than 4 wk to an area where polio is endemic or epidemic, that is, those who

cannot receive two doses of IPV before departure. Individuals who are immunocompromised or contacts of an immunocompromised person should never receive OPV. Unvaccinated adults who are at increased risk of exposure to poliovirus and who cannot complete the recommended IPV regimen (0, 1–2, and 6–12 mo) should receive three doses of IPV given at least 4 wk apart.

Varicella.

All children 12 mo of age or older who have no history of varicella vaccination or chickenpox should be vaccinated unless there is a contraindication to vaccination (see Chapter 282). Infants younger than 6 mo of age are generally protected by maternal antibodies. Children younger than 13 yr of age require only one dose; children 13 yr of age or older require two doses separated by 4–8 wk.

SPECIAL VACCINATIONS FOR TRAVEL

Cholera.

Cholera is present in many developing countries, but the risk of infection among travelers to these countries is very low. The killed cholera vaccine formerly used in the United States has less than 50% efficacy and is not recommended by the CDC or the World Health Organization (WHO) for travel to or from cholera-infected areas. It is no longer generally available. No country or territory currently requires cholera vaccination, but rarely a local authority may require documentation of vaccination; in such cases, a single dose is sufficient to satisfy local requirements. If cholera vaccine is given, it should be given at least 3 wk apart from yellow fever vaccination. A new oral live cholera vaccine is available in Canada and many European countries for use in children age 2 yr and older; it is not currently available in the United States.

Hepatitis A.

Hepatitis A virus is endemic in most of the world, and travelers are at risk even if their travel is restricted to the usual tourist routes. Hepatitis A infection can occur as a result of eating shellfish harvested from sewage-contaminated waters, eating unwashed vegetables or fruits, or eating food prepared by an asymptomatic carrier of hepatitis A virus. Young children infected with hepatitis A are often asymptomatic, but they may transmit infection to older children and adults, who are more likely to develop clinical hepatitis. Hepatitis A immunization or immune globulin prophylaxis is recommended for children traveling to a developing country and should probably be given to all traveling children regardless of destination, because few areas carry no risk of this infection.

The two inactivated hepatitis A vaccines currently available in the United States are approved by the Food and Drug Administration only for children 2 yr of age and older. Hepatitis A vaccine in two doses intramuscularly (0.5?mL for 2–17 yr of age; 1?mL for =18 yr of age), given 6–12 mo apart, is recommended for children traveling to countries with intermediate or high hepatitis A endemicity (areas other than the United States, Canada, Australia, New Zealand, Japan, Western Europe, and Scandinavia). Protective immunity develops 2–4 wk after receiving the initial vaccine dose. A combined, three-dose hepatitis A and hepatitis B vaccine is now available in the United States, but it is licensed for use only in adults older than 18 yr of age.

Children younger than 2 yr of age and children who will be traveling to an endemic area in less than 2 wk should receive intramuscular immune globulin (IG). For short-term protection (1–2 mo), 0.02?mL/kg of IG is given IM; for long-term protection (3–5 mo), 0.06?mL/kg of IG is given IM and repeated every 5 mo while exposure to hepatitis A continues. Immune globulin can be administered at the same time as the inactivated vaccine but should be given at a separate site and in a separate syringe. If a child requires MMR or varicella immunization, these live-attenuated viral vaccines should be given either 2 wk before or 3 mo after IG administration.

Influenza.

The risk for exposure to influenza during international travel varies depending on the time of year, destination, and intermingling of persons from different parts of the world where influenza may be circulating. In the tropics, such as the Caribbean, influenza can occur throughout the year. In the temperate regions of the Southern Hemisphere, including Australia and South America, most activity occurs from April through September. In the Northern Hemisphere, including the United States and Canada, influenza generally occurs from November through March. Influenza vaccination is recommended for children = 6 mo of age at increased risk for complications of influenza, including children of any age with chronic medical conditions such as chronic cardiac, renal or pulmonary disease, immunosuppressive conditions or therapy, HIV infection, sickle cell disease, and diabetes mellitus (see Chapter 282).

Japanese Encephalitis.

Japanese encephalitis is a disease transmitted by mosquitoes in rural areas of Asia, where people are in close proximity to livestock. Asymptomatic cases outnumber symptomatic cases by at least 200 to 1, but when symptomatic the disease has a 10–70% case fatality rate. The risk in travelers is extremely low, less than 1 case/million travelers, but the risk is highest in children. The disease occurs primarily from June to September in temperate zones and throughout the entire year in tropical zones. Vaccination is recommended for travelers planning visits of greater than 1 mo to rural areas of Asia where the disease is endemic, especially areas of rice or pig farming, or shorter visits to such an area if the traveler will frequently be outdoors (e.g., camping or hiking). Risk of infection can be greatly reduced by following the standard precautions to avoid mosquito bites. Parents of very young

children should be discouraged from traveling with their children to high-risk areas.

The inactivated Japanese encephalitis vaccine is licensed for children 1 yr of age and older. It is administered in three doses (0.5?mL for 1–3 yr of age; 1?mL for 3 yr of age and older) subcutaneously on days 0, 7, and 30, or on days 0, 7, and 14 in an accelerated dosing schedule. The vaccine has an efficacy of more than 95%, but hypersensitivity reactions occur in up to 0.6% of vaccine recipients; 1 in 1,000 vaccinees have urticarial reactions or facial or oropharyngeal angioedema that may occur within minutes or up to 2 wk after vaccination. The series should be completed 2 wk before travel so that any adverse reactions to the vaccine can be observed and treated.

Meningococcus.

Neisseria meningitidis causes epidemic and endemic disease worldwide (see Chapter 176). Most cases occur in the "meningitis belt" of sub-Saharan Africa between December and June. Epidemics have also occurred in the Indian subcontinent and Saudi Arabia. Cases in American travelers are rare, and vaccination is indicated primarily in travelers to an area with an active outbreak or those who may have prolonged contact with the local population in an endemic area, especially in crowded conditions. Saudi Arabia requires all pilgrims to Mecca to have documentation of meningococcal vaccination 10 or more days but less than 3 yr before arrival. Serogroup A is the most common cause of epidemics outside the United States, but serogroup C and, rarely, serogroup B have also been associated with epidemics.

The only meningococcal vaccine currently available in the United States is the quadrivalent polysaccharide A/C/Y/W-135 vaccine. The vaccine is ineffective against serogroup A in infants younger than 3 mo of age and may be only partially

effective against this serogroup in children 3–11 mo of age. Children younger than 2 yr of age are not protected against the other serogroups. The meningococcus vaccine (0.5?mL SC) is recommended for children age 2 yr and older who are at risk for meningococcal disease caused by a vaccine serogroup, as well as for children 3 mo of age and older who are at risk for serogroup A meningococcal disease. Children vaccinated before 4 yr of age should be revaccinated after 2–3 yr if they remain in an endemic area. Highly effective meningococcal conjugate vaccines against serogroups A and C are available in Europe but have not yet been licensed for use in the United States.

Rabies.

The risk of rabies is currently the highest in countries where rabies in dogs is uncontrolled, including Colombia, Ecuador, El Salvador, Guatemala, India, Mexico, Nepal, Philippines, Thailand, and Vietnam. Rabies is also endemic in most other countries of Africa, Asia, and Central and South America. Children are at particular risk because facial bites are more common in children. Pre-exposure prophylaxis should be considered if a child will be in an endemic area for longer than 1 mo or will be traveling to an area where rapid, effective postexposure prophylaxis may not be available. An animal bite in a rabies-endemic area is a medical emergency. Immediate medical care should be sought at a facility that can administer appropriate postexposure rabies prophylaxis. If possible, the animal in question should be caught and quarantined for 10 days of observation for signs of rabies. Postexposure prophylaxis is required even for individuals who received pre-exposure vaccination.

Three inactivated rabies vaccines are available in the United States for pre-exposure vaccination: the human diploid cell vaccine (HDCV), the rabies vaccine absorbed (RVA), and the purified chick embryo cell vaccine (PCEC). Pre-exposure prophylaxis is given either intramuscularly (HDCV, RVA, or PCEC) as three doses (1?mL) on days 0, 7, and 28, or intradermally (HDCV) as three doses (0.1?mL) on days 0, 7 and 28. Postexposure prophylaxis is given as five doses (1?mL) of HDCV, RVA, or PCEC vaccine intramuscularly on days 0, 3, 7, 14, and 28 if previously unvaccinated and two doses (1?mL) intramuscularly on days 0 and 3 if previously vaccinated. Previously unvaccinated individuals should receive rabies immune globulin (RIG) (20?IU/ kg, with as much of the dose as possible infiltrated around the wound site) at the time of initial postexposure prophylaxis. Previously vaccinated individuals should not receive RIG. Children receiving mefloquine or chloroquine may have limited immune reactions to intradermal rabies vaccine and should be vaccinated intramuscularly. Purified cell culture–derived vaccines are not always available abroad; travelers should be aware that rabies vaccines derived from neural tissue carry an increased risk of adverse reactions, often with neurologic sequelae. Unpurified or purified equine RIG preparations are still used in some developing countries and are also associated with a higher risk of severe reactions, including serum sickness and anaphylaxis. If rabies prophylaxis is initiated abroad, neutralizing titers should be checked on return and immunization completed with a cell culture–derived vaccine.

Tuberculosis.

The risk of tuberculosis in the typical traveler is low. All children traveling for prolonged periods to high-risk areas should have tuberculin skin testing done before and after travel. Immunization with bacille Calmette-Guérin (BCG) is controversial. It is not frequently used in the United States, but some authorities believe it should be given to children, especially infants, who will reside for a long time in an area with a high prevalence of tuberculosis or with multidrug-resistant tuberculosis because it is highly protective against meningeal and miliary tuberculosis in children.

Typhoid.

Salmonella ser. Typhi (*Salmonella typhi*) infection, or typhoid fever, is common in many developing countries in Asia, Africa, and Latin America (see Chapter 181.2). Typhoid vaccination is recommended for children traveling to the Indian subcontinent, the area of highest risk, and for individuals traveling to endemic areas who are at higher risk of infection: long-term travelers (those traveling for >4 wk), backpackers, and travelers staying with friends or relatives in developing countries. Vaccination should be strongly considered for all children traveling to endemic areas, especially if exposure to contaminated food and water is likely.

Two typhoid vaccines, the intramuscular Vi-polysaccharide vaccine and oral Ty21a strain live-attenuated vaccine, are recommended for use in children in the United States. The intramuscular Vi-polysaccharide vaccine is licensed for use in children 2 yr of age and older. It is given as a single dose (0.5?mL IM), with a booster every 2 yr. It can be given any time before departure, but it should ideally be administered 1 mo or more before travel. The oral Ty21a vaccine can only be used in children 6 yr of age and older. The oral vaccine is given in four doses over a 1-wk period: one enteric-coated capsule is swallowed whole with a cool drink, at least 1 hour before a meal, every other day until the four doses are completed. The course should be repeated as a booster every 5 yr if there is continued exposure to typhoid. Antibiotics and the antimalarial drugs mefloquine and chloroquine inhibit the immune response to the oral Ty21a vaccine. The vaccine should not be given for 24?hr after the most recent dose of antibiotic or mefloquine or chloroquine. Oral Ty21a vaccine should not be given to immunocompromised children; these children should receive the intramuscular Vi-polysaccharide vaccine. An early-generation heat-phenol–inactivated vaccine (strain Ty2) is efficacious and remains available, but use of this vaccine is no longer recommended owing to the high incidence of adverse reactions.

Yellow Fever.

Yellow fever (see Chapter 247) is a mosquito-borne viral illness resembling other viral hemorrhagic fevers (see Chapter 248) but with more prominent hepatic involvement. Yellow fever is present in tropical areas of South America and Africa. In the past 15 years, Nigeria and Peru have reported the greatest number of cases.

Yellow fever vaccination is indicated in children older than 9 months traveling to an endemic area. Some countries require yellow fever vaccination by law for travelers arriving from endemic areas. Some African countries require evidence of vaccination from all entering travelers. Current recommendations can be obtained by contacting state or local health departments or the Division of Vector-Borne Infectious Diseases of the CDC (telephone: 404-332-4555; or website: www.cdc.gov). Most countries accept a medical waiver for children who are too young to be vaccinated (<4 mo of age) and for individuals with a contraindication to vaccination, such as immunodeficiency. Children with asymptomatic HIV infection may be vaccinated if exposure to yellow fever virus cannot be avoided.

Yellow fever vaccine (0.5?mL SC), a live-attenuated vaccine (17D strain) developed in chick embryos, is safe and highly effective in children older than 9 mo of age, but in young infants it is associated with an increased risk of encephalitis (0.4%) and other severe reactions. Yellow fever vaccine should never be administered to infants younger than 4 mo of age; infants 4–6 mo of age should be vaccinated only in consultation with the CDC; infants 6–9 mo of age should be vaccinated only if they cannot avoid traveling to areas with an ongoing epidemic. Children with a history of anaphylactic reactions to eggs should also not receive yellow fever vaccine. Long-lived, perhaps lifetime immunity develops to this vaccine; however, international

travel certificates require proof of immunization within 10 yr. Cholera vaccination is not currently recommended in the United States but if given should be given 3 wk apart from yellow fever vaccination.

Traveler's Diarrhea.

Traveler's diarrhea, characterized by a twofold or greater increase in the frequency of unformed bowel movements, occurs in as many as 40% of all travelers overseas. Children, especially those younger than 3 yr of age, have a higher incidence of diarrhea, more severe symptoms, and more prolonged symptoms than adults. Traveler's diarrhea is usually acquired through ingestion of fecally contaminated food and water. Diverse infectious agents (bacteria, viruses, and parasites) have been associated with traveler's diarrhea; enterotoxigenic *E. coli* is still the most frequent cause. Other bacterial causes include *Shigella, Salmonella, Campylobacter, Vibrio cholerae, Vibrio parahaemolyticus, Aeromonas hydrophilia,* and *Plesiomonas shigelloides.* Protozoan infections such as *Entamoeba histolytica, Giardia lamblia, Cryptosporidium parvum,* and *Isospora* are more common in long-term travelers. Rotavirus has also been associated with traveler's diarrhea. The most important risk factor for traveler's diarrhea is the country of destination. High-risk areas (attack rates of 25–50%) include developing countries of Latin America, Africa, the Middle East, and Asia. Intermediate risk occurs in the Mediterranean, China, and Israel. Low-risk areas include North America, Northern Europe, Australia, and New Zealand. Immunocompromised children, including children with HIV, are at increased for complications from bacterial causes of traveler's diarrhea, particularly *Salmonella*. Careful selection and preparation of food and water can significantly reduce the risk of developing traveler's diarrhea (see “General Travel Preparation”). Chemoprophylactic agents for traveler's diarrhea are not recommended for children.

Dehydration is the greatest threat presented by a diarrheal illness in a small child. Parents should be made aware of the symptoms and signs of dehydration. Prepackaged WHO/UNICEF oral rehydration solution (ORS) packets, which are available at stores or pharmacies in almost all developing countries, should be part of a child's travel kit. ORS should be mixed as directed with bottled or boiled water and given slowly, as tolerated, to the child. Antimotility agents such as diphenoxylate (Lomotil) and loperamide (Imodium) should be avoided in young children; loperamide (2?mg tid PO) may be useful for children older than 8 yr of age if they do not have fever or bloody stools. Bismuth subsalicylate (5?mL for 3–5 yr of age; 10?mL for 6–8 yr of age; 15?mL for 9–11 yr of age; 30?mL for =12 yr of age) as often as every 30?min for eight doses, with no more than eight doses/24?hr, decreases the rate of stooling and shortens the duration of illness. Higher doses of bismuth subsalicylate should be avoided because of concerns of salicylate toxicity. Bismuth subsalicylate should not be used if the child may have influenza or is in an area experiencing an influenza outbreak, because there is an increased risk of Reye syndrome in children with influenza who receive salicylate therapy.

Increased antibiotic resistance among the organisms that cause traveler's diarrhea has led to new recommendations for presumptive treatment of traveler's diarrhea. Presumptive self-treatment is usually recommended for adults, and most experts agree that it should also be given to children. For adults 18 yr of age and older the recommended regimen is ciprofloxacin (500?mg), norfloxacin (400?mg), or ofloxacin (300?mg) orally twice daily for 3 days. The recommended drug for children age 2 mo or older was formerly trimethoprim-sulfamethoxazole (TMP-SMZ), but increased

bacterial resistance has diminished its efficacy. Azithromycin (either 10?mg/kg/day for 3 days or 10?mg/kg/day 1, 5?mg/kg days 2–5) is not specifically approved for the treatment of diarrhea, but it is highly effective against most pathogens that cause traveler's diarrhea and is probably the drug of choice for children with traveler's diarrhea. Antimicrobial therapy for traveler's diarrhea in infants and young children should be administered in consultation with a physician. This is particularly true if the illness is severe, persists for longer than 3 days, or is associated with bloody stools, temperature greater than 102°F, chills, vomiting, or moderate to severe dehydration.

Malaria Chemoprophylaxis.

Malaria, a mosquito-borne infection, is the leading parasitic cause of death in children worldwide (see Chapter 264). Of the four *Plasmodium* species that infect humans, *P. falciparum* causes the greatest morbidity and mortality. Each year, more than 8 million U.S. citizens visit parts of the world where malaria is endemic (sub-Saharan Africa, Central and South America, India, Southeast Asia, Oceania). Given the major resurgence of malaria, physicians in developed countries are increasingly required to give advice on prevention, diagnosis, and treatment of malaria. The CDC maintains updated information at www.cdc.gov/travel/index.htm, as well as a malaria hotline for physicians (770-488-7788). It is important to check this updated information because continuing changes in the risk of developing malaria in many areas of the world, changing *Plasmodium* resistance patterns, and the availability of new antimalarial medications result in regular modifications of recommendations for prophylaxis and treatment.

Avoidance of mosquitoes and barrier protection from mosquitoes are an important part of malaria prevention for travelers to endemic areas. The *Anopheles* mosquito feeds from dusk to dawn. Travelers should remain in well-screened areas, wear clothing that covers most of the body, sleep under a bed net (ideally one impregnated with permethrin), and use insect repellents with DEET during these hours. Parents should be discouraged from taking a young child on a trip that will entail evening or night-time exposure in rural areas of countries with chloroquine- or multidrug-resistant *P. falciparum*.

Chemoprophylaxis is the cornerstone of malaria prevention for nonimmune children and adults who travel to malaria endemic areas, but it is not a replacement for other protective measures because no chemoprophylaxis regimen guarantees complete protection against malaria. Travelers often do not take malaria prophylaxis as prescribed; frequently they do not take it at all. They are more likely to use prophylactic antimalarial drugs if their physicians provide appropriate recommendations and education before departure. However, in one survey, only 14% of persons who sought medical advice obtained correct information about malaria prevention and prophylaxis.

Resistance of *P. falciparum* to the traditional chemoprophylactic agent, chloroquine, is rapidly increasing worldwide, and in most areas of the world other agents must be used (Table 285–2). Factors that must be considered in choosing appropriate chemoprophylaxis medications and dosing schedules include age of the child, travel itinerary (including whether the child will be traveling to areas of risk within a particular country and whether chloroquine-resistant *P. falciparum* is present in the country), vaccinations being given (particularly rabies and oral typhoid, see earlier), allergic or other known adverse reactions to antimalarial agents, and the availability of medical care during travel.

Weekly mefloquine is the drug of choice for malaria chemoprophylaxis in children and adults traveling to areas with chloroquine-resistant *P. falciparum*. Although mefloquine is FDA-approved only for children weighing more than 15 kg, the CDC recommends mefloquine prophylaxis for all children

TABLE 285-2 -- Chemoprophylaxis of Malaria in Children

Area	Drug	Dosage (Oral)
Chloroquine-resistant area	Mefloquine[*]	<15 kg: 4.6?mg base (5 mg salt)/kg/wk
		15–19 kg: ¼ tablet/wk
		20–30 kg: ½ tablet/wk
		31–45 kg: ¾ tablet wk
		>45 kg: 1 tablet/wk (228-mg base)
	Doxycyline[†]	2?mg/kg/24 hr (maximum: 100?mg)
	Atovaquone/proguanil[‡] (Malarone)	Pediatric tablets: 62.5?mg atovaquone/25?mg proguanil
		Adult tablets: 250?mg proguanil/100?mg proguanil
		11–20 kg: 1 *pediatric* tablet once daily
		21–30 kg: 2 *pediatric* tablets once daily
		31–40 kg: 3 *pediatric* tablets once daily
		>40 kg: 1 *adult* tablet once daily
		5?mg base/kg/wk (maximum: 300?mg base)

Chloroquine-sensitive area	Chloroquine phosphate *plus*	<1 yr: ¼ tablet
	Pyrimethamine/sulfadoxine for presumptive treatment§	1–3 yr: ½ tablet
		4–8 yr: 1 tablet
		9–14 yr: 2 tablets
		>14 yr: 3 tablets

**Chloroquine and mefloquine should be started 1 wk before departure and continued 4 wk after last exposure.*
†Doxycycline should be started 1 day before departure and continued for 4 wk after last exposure. Do not use in children <8 yr old or pregnant women.
‡Atovaquone/proguanil (Malarone) should be started 1 to 2 days before departure and continued for 7 days after last exposure.
§Sulfadoxine/pyrimethamine resistance is present in South America, Africa, and Asia. It can be used for presumptive treatment if medical care is not available within 24 hr, while promptly seeking medical care.

regardless of weight because the risk of acquiring severe malaria outweighs the risk of potential mefloquine toxicity. Adults have 10–25% incidence of sleep disturbance and dysphoria with mefloquine, but these side effects appear to be less common in children. Other potential side effects of mefloquine therapy include nausea and vomiting. The lack of a liquid or suspension formulation sometimes makes chloroquine and mefloquine administration difficult; they are better tolerated by children if they are “disguised” in other foods. Individuals with epilepsy or neuropsychiatric disorders should not take mefloquine. A fixed combination of atovaquone and proguanil (trade name: Malarone) was recently approved by the FDA for the prophylaxis and treatment of chloroquine-resistant *P. falciparum* malaria in adults and children. Atovaquone/proguanil is highly effective chemoprophylaxis for travelers to chloroquine-resistant malaria endemic areas. Adverse effects are infrequent, mild (abdominal pain, vomiting, and headache) and rarely result in discontinuation of the medication. Atovaquone/ proguanil prophylaxis must be taken every day, so it is better suited for prophylaxis during short periods of exposure. Daily doxycycline is an alternative chemoprophylaxis regimen for chloroquine-resistant *P. falciparum* malaria that is considerably less expensive than atovaquone/proguanil. Doxycycline has been used extensively and is highly effective, but it cannot be used in children younger than 8 years old, and side effects (nausea, vomiting, photosensitivity, vaginal candidiasis) are not uncommon. Individuals given doxycycline prophylaxis should be warned to decrease exposure to direct sunlight to minimize the possibility of photosensitivity. Primaquine has also been used successfully as chemoprophylaxis, but there are limited data about its use in nonimmune children. Chloroquine, chloroquine-proguanil, and azithromycin do not provide adequate protection for children traveling to a chloroquine-resistant malaria endemic area.

Weekly chloroquine is the drug of choice for malaria chemoprophylaxis in those areas of the world where *P. falciparum* remains fully chloroquine-sensitive (Haiti, the Dominican Republic, Central America north of the Panama Canal, and some countries in the Middle East). Updated information is available at www.cdc.gov/travel.

On leaving a malaria-endemic area after a prolonged visit, travelers may require treatment with primaquine (0.3?mg/kg base or 0.5?mg/kg salt daily for 14 days) to eliminate the extraerythrocytic forms of *P. vivax* and *P. ovale* to prevent relapses. Primaquine can cause severe hemolysis in G6PD-deficient individuals. Individuals must always be screened for G6PD-deficiency before primaquine is prescribed.

Small amounts of antimalarial drugs are secreted into breast milk of lactating women. The amounts of transferred drug are not considered to be either harmful or sufficient to provide adequate prophylaxis against malaria. Prolonged infant exposure to doxycycline via breast milk is not advisable.

The Returning Traveler.

Post-travel evaluations are part of travel medicine and continuing care. Children who will be traveling abroad for a prolonged period of time (>6 mo) should receive tuberculin skin testing before and after travel and should be tested for asymptomatic gastrointestinal parasitic infections on their return. Physicians unfamiliar with diseases that occur in developing countries often misdiagnose the cause of illness in a child returning from travel abroad. Fever is a particularly worrisome symptom: malaria and typhoid are the two most common causes of fever in children returning from travel to developing countries, but dozens of other illnesses acquired in these countries may cause fever. Malaria must be considered in the evaluation of any fever that develops within 1 yr, and particularly within the first 2 mo, after travel to malaria-endemic areas. Children returning from international travel who have specific signs and symptoms of illness, such as fever, rash, or chronic diarrhea, should see a pediatric travel medicine or infectious disease specialist.

Part 17 - The Digestive System

Section 1 - *Clinical Manifestations of Gastrointestinal Disease*

Robert Wyllie

Chapter 286 - Normal Digestive Tract Phenomena

Gastrointestinal function varies with maturity; a symptom that might be abnormal at an older age, such as regurgitation, is normal in an infant. A fetus can swallow amniotic fluid as early as 12 wk gestation, but nutritive sucking in neonates first develops at about 34 wk gestation. The coordinated oral and pharyngeal movements necessary for swallowing solids develop within the first few months of life in term infants. Before this time, the tongue thrust is upward and outward to express milk from the nipple instead of a backward motion, which propels solids toward the esophageal inlet. By 1 mo of age, infants appear to show preferences for sweet and salty foods. Infants' interest in solids increases at about 4 mo of age. The current recommendation to begin solids at 6 mo of age is based on nutritional concepts rather than maturation of the swallowing process (see Chapter 41). Infants swallow air during feeding and must be stimulated to burp to prevent gaseous distention of the stomach.

A number of normal anatomic variations may be noted in the mouth. A short lingual frenulum (“tongue-tie”) may be worrisome to parents but only rarely interferes with eating or speech, generally requiring no treatment. Surface furrowing of the tongue (i.e., a geographic or scrotal tongue) is usually a normal finding. A bifid uvula may be normal or associated with a submucous cleft of the soft palate.

Regurgitation, the result of gastroesophageal reflux, occurs commonly in the first year of life. Effortless regurgitation may dribble out of an infant's mouth but also may

be forceful. In an otherwise healthy infant with regurgitation, volumes of emesis are commonly about 15–30?mL but may occasionally be larger. Most often, the infant remains happy, although possibly hungry, after an episode of regurgitation. Episodes may occur from less than one to several times per day. Regurgitation gradually resolves in 80% of infants by 6 mo of age and in 90% by 12 mo. If complications develop or regurgitation persists, gastroesophageal reflux is considered pathologic rather than merely developmental and deserves further evaluation and treatment. Complications include failure to thrive, pulmonary disease (apnea or aspiration pneumonitis), and esophagitis with its sequelae (see Chapters 304 and 305).

Infants and young children may be erratic eaters; this may be a worry to parents. A toddler may eat insatiably or refuse to consume food during a meal. There is also a tendency for toddlers and young children to eat only a limited variety of foods. Parents should be encouraged to view nutritional intake over several days and not be overly concerned about individual meals. Infancy and adolescence are periods of rapid growth; high nutrient requirements for growth may be associated with voracious appetites. The reduced appetite of toddlers and preschool children is often a worry to parents who are used to the relatively greater dietary intake during infancy. Demonstration of age-appropriate growth on a growth curve is reassuring.

The *number, color*, and *consistency of stools* may vary greatly in the same infant and between infants of similar age without apparent explanation. The earliest stools after birth consist of meconium, a dark, viscous material that is normally passed within the first 48?hr of life. With the onset of feeding, meconium is replaced by green-brown transition stools, often containing curds, and, after 4–5 days, by yellow-brown milk stools. Stool frequency is extremely variable in normal infants and may vary from none to seven per day. Breast-fed infants may have frequent small, loose stools early (transition stools) and then after 2–3 wk may have very infrequent soft stools. It is possible for a nursing infant not to pass any stool for 1–2 wk and then to have a normal soft bowel movement. The color of stool has little significance except for the presence of blood or absence of bilirubin products (white-gray rather than yellow-brown). The presence of vegetable matter, such as peas or corn, in the stool of an older infant or toddler ingesting solids is normal and suggests poor chewing and not malabsorption. A pattern of intermittent loose stools, known as “toddler's diarrhea,” occurs commonly between 1 and 3 yr of age. These otherwise healthy growing children often drink excessive carbohydrate-containing beverages and eat snacks throughout the day. The stools typically occur during the day and not overnight. The volume of fluid intake is often excessive; limiting sugar-containing beverages and increasing fat in the diet often leads to resolution of the pattern of loose stools.

A *protuberant abdomen* is often noted in infants and toddlers, especially after large feedings. This may result from the combination of weak abdominal musculature, relatively large abdominal organs, and lordotic stance. In the 1st yr of life, it is common to palpate the liver 1 to 2?cm below the right costal margin. The normal liver is soft in consistency and percusses to normal size for age. A Riedel lobe is a thin projection of the right lobe of the liver that may be palpated low in the right lateral abdomen. A soft spleen tip may also be palpable as a normal finding. In thin young children, the vertebral column is easily palpable and an overlying structure may be mistaken for a mass. Commonly, pulsation of the aorta can be appreciated. Normal stool can often be palpated in the left lower quadrant in the descending or sigmoid colon.

Blood loss from the gastrointestinal tract is never normal, but swallowed blood may be misinterpreted as gastrointestinal bleeding. Maternal blood may be ingested at the time of birth or later by a nursing infant if there is bleeding near the mother's

nipple. Nasal or oropharyngeal bleeding is occasionally mistaken for gastrointestinal bleeding (see Chapter 92.4). Red dyes in foods or drinks may turn the stool red but do not produce a positive test result for occult blood.

Jaundice is common in neonates, especially among premature infants, and usually results from the inability of an immature liver to conjugate bilirubin, leading to an elevated indirect component (see Chapter 91.3). Persistent elevation of indirect bilirubin levels in nursing infants may be a result of breast milk jaundice, which is usually a benign entity in full-term infants. Elevated direct bilirubin is never normal and suggests liver disease, although in infants it may be a result of extrahepatic infection (e.g., urinary tract infection). The direct bilirubin fraction should account for no more than 15% to 20% of the total bilirubin content. Indirect hyperbilirubinemia, which occurs commonly in normal newborns, tends to tint the sclerae and skin golden yellow, whereas direct hyperbilirubinemia produces a greenish yellow hue.

Chapter 287 - Major Symptoms and Signs of Digestive Tract Disorders

Disorders of organs outside the gastrointestinal tract can produce symptoms and signs that mimic digestive tract disorders and should be considered in the differential diagnosis (Box 287–1). Understanding the potential pathogenesis of symptoms will allow rational diagnosis and management decisions. In children with normal growth and development, treatment may be initiated without a formal evaluation based on a presumptive diagnosis after taking a history and performing a physical examination. Poor weight gain or weight loss is often associated with a significant pathologic process and usually necessitates a more formal evaluation.

Dysphagia.

Dysphagia, or difficulty swallowing, may be caused by a structural defect or motility disorder. Structural defects that cause a fixed impediment to the food bolus arise from narrowing within the esophagus, such as a stricture, web, or tumor. Extrinsic obstruction is most often caused by a vascular ring. Structural defects typically cause more problems swallowing solids than liquids. Most nonstructural causes of dysphagia are caused by motility abnormalities of the oropharynx or the esophagus. Swallowing is a complex process that starts in the mouth with mastication and lubrication of food that is formed into a bolus. The bolus is pushed to the pharynx by the tongue. The pharyngeal phase of swallowing is rapid and involves protective mechanisms to prevent food from entering the airway. The epiglottis is lowered over the larynx while the soft palate is elevated against the nasopharyngeal wall; there is a temporary arrest of respiration while the upper esophageal sphincter opens to allow the bolus to enter the esophagus. In the esophagus, peristaltic coordinated muscular contractions push the food bolus toward the stomach. The lower esophageal sphincter relaxes shortly after the upper esophageal sphincter so liquids that rapidly clear the esophagus enter the stomach without resistance.

Dysphagia during the oropharyngeal phase of swallowing is termed *transfer dysphagia* and is usually associated with neuromuscular disorders (cerebral palsy). The sensation that something is stuck in the upper esophagus is globus (formerly termed *globus hystericus*). Globus is usually associated with gastroesophageal reflux.

Box 287-1. Some Nondigestive Tract Causes of Gastrointestinal Symptoms in Children

ANOREXIA

- Systemic disease (e.g., inflammatory, neoplastic)
- Cardiorespiratory compromise
- Iatrogenic—drug therapy, unpalatable therapeutic diets
- Depression
- Anorexia nervosa

VOMITING

- Inborn errors of metabolism
- Medications (erythromycin, chemotherapy)
- Increased intracranial pressure
- Brain tumor
- Infection (e.g., urinary tract)
- Labyrinthitis
- Adrenal insufficiency
- Pregnancy
- Psychogenic
- Abdominal migraine
- Toxins

DIARRHEA

- Infection (e.g., otitis media, urinary)

DIARRHEA

Infection (e.g., otitis media, urinary)

Uremia

Medications (antibiotics, cisapride)

Tumors (neuroblastoma)

Pericarditis

CONSTIPATION

Hypothyroidism

Spina bifida

Psychomotor retardation

Dehydration (e.g., diabetes insipidus, renal tubular lesions)

Medications (narcotics)

Lead poisoning

Infant botulism

ABDOMINAL PAIN

Pyelonephritis, hydronephrosis, renal colic

Pneumonia

Pelvic inflammatory disease

Porphyria

Angioedema

Endocarditis

Abdominal migraine

Familial Mediterranean fever

Sexual or physical abuse

Systemic lupus erythematosus

Familial Mediterranean fever

Sexual or physical abuse

Systemic lupus erythematosus

School phobia

Sickle cell crisis

Vertebral disk inflammation

Medications (NSAIDs)

Pelvic osteomyelitis

ABDOMINAL DISTENTION OR MASS

Ascites (e.g., nephrotic syndrome, neoplasm, heart failure)

Discrete mass (e.g., Wilms' tumor, hydronephrosis, neuroblastoma, mesenteric cyst, hepatoblastoma, lymphoma)

Pregnancy

JAUNDICE

Hemolytic disease

Urinary tract infection

Sepsis

Hypothyroidism

Panhypopituitarism

When dysphagia is associated with a delay in passage through the esophagus, a child may be able to point to the level of the chest where the delay occurs; esophageal symptoms may be referred to the suprasternal notch. Therefore, when a child points to the suprasternal notch, the impaction may be found anywhere in the esophagus.

TRANSFER DYSPHAGIA.

A complex sequence of neuromuscular events is involved in the transfer of foods to

the upper esophagus. Suckling requires the lips to form a tight seal about

the nipple while the tongue is displaced posteriorly. As the glottis closes to guard the airway, the soft palate rises to close the nasopharynx, the cricopharyngeal muscles relax, and food passes to the back of the pharynx. Solids similarly require coordinated actions; for large chunks of solid food, jaw movement and teeth become factors to consider. Salivary secretions, stimulated by the anticipation and act of ingestion, lubricate foods as they pass through the mouth. It is abnormalities of the muscles involved in the ingestion process, their innervation, strength, or coordination that usually cause transfer dysphagia in infants and children. In such cases, an oropharyngeal problem is almost always part of a more generalized neurologic or muscular problem (botulism, diphtheria, cerebral palsy). Painful oral lesions, such as acute viral stomatitis or trauma, occasionally interfere with ingestion. If the nasal air passage is seriously obstructed, the need for air causes severe distress when suckling. Although severe structural, dental, and salivary abnormalities would be expected to create difficulties, ingestion proceeds relatively well in most affected children if they are hungry.

NONTRANSFER DYSPHAGIA.

Primary motility disorders causing impaired peristaltic function and dysphagia are rare in children. Motility of the distal esophagus is disordered after repair of tracheoesophageal fistula. Abnormal motility may accompany collagen vascular disorders. Achalasia rarely occurs in children. Esophageal web, tracheobronchial remnant, or vascular ring may cause dysphagia in infancy. An esophageal stricture secondary to chronic gastroesophageal reflux and esophagitis occasionally presents with dysphagia as the first manifestation. A Schatzki ring is another mechanical cause of recurrent dysphagia presenting after infancy. An esophageal foreign body or a stricture secondary to a caustic ingestion also causes dysphagia.

Regurgitation.

Regurgitation is the effortless movement of stomach contents into the esophagus and mouth. It is not associated with distress, and infants with regurgitation are often hungry immediately after an episode. The lower esophageal sphincter prevents reflux of gastric contents into the esophagus (see Chapter 304). Regurgitation is a result of gastroesophageal reflux through an incompetent or, in infants, immature lower esophageal sphincter. This is often a developmental process, and regurgitation or “spitting” resolves with maturity. Regurgitation should be differentiated from vomiting, which denotes an active reflex process with a different differential diagnosis (Table 287–1).

Anorexia.

Hunger and satiety centers are located in the hypothalamus; it seems likely that afferent nerves from the gastrointestinal tract to these brain centers are important determinants of the anorexia that characterizes many diseases of the stomach and intestine. Satiety is stimulated by distention of the stomach or upper small bowel, the signal being transmitted by sensory afferents, which are especially dense in the upper gut. Chemoreceptors in the intestine, influenced by the assimilation of nutrients, also affect afferent flow to the appetite centers. Impulses reach the hypothalamus from higher centers, possibly influenced by pain or the emotional disturbance of an intestinal disease. Other regulatory factors include hormones, leptin, and plasma glucose, which in turn reflect intestinal function.

Vomiting.

Vomiting is a highly coordinated reflex process that may be preceded by increased salivation and begins with involuntary retching. Violent descent of the diaphragm and constriction of the abdominal muscles with relaxation of the gastric cardia actively force gastric contents back up the esophagus. This process is coordinated in the medullary vomiting center, which is influenced directly by afferent innervation and indirectly by the chemoreceptor trigger zone and higher central

TABLE 287-1 -- Differential Diagnosis of Emesis During Childhood

Infant	Child	Adolescent
Common		
Gastroenteritis	Gastroenteritis	Gastroenteritis
Gastroesophageal reflux	Systemic infection	GERD
Overfeeding	Gastritis	Systemic infection
Anatomic obstruction	Toxic ingestion	Toxic ingestion
Systemic infection	Pertussis syndrome	Gastritis
Pertussis syndrome	Medication	Sinusitis

	Achalasia	Cyclic vomiting (migraine)
	Cyclic vomiting (migraine)	Biliary colic
		Renal colic
	Esophageal stricture	
	Duodenal hematoma	
	Inborn error of metabolism	

GERD = gastroesophageal reflux disease.

nervous system (CNS) centers. Many acute or chronic processes can cause vomiting (Boxes 287–1 and 287–2).

Vomiting caused by obstruction of the gastrointestinal tract is probably mediated by intestinal visceral afferent nerves stimulating the vomiting center (see Box 287–1). If obstruction occurs below the second part of the duodenum, vomitus is usually bile stained. With repeated vomiting in the absence of obstruction, however, duodenal contents are refluxed into the stomach and the emesis may become bile stained. Nonobstructive lesions of the digestive tract can also cause vomiting; most diseases of the upper bowel, pancreas, liver, or biliary tree are capable of provoking emesis. CNS or metabolic derangements may lead to severe, persistent emesis.

Cyclic vomiting is a syndrome with numerous episodes of vomiting (about nine episodes/mo) interspersed with well intervals. The onset is usually between 3–5 yr of age; the episodes last 2–3 days, with four or more emesis episodes per hour. Patients may have a prodrome of nausea, lethargy, and headache or fever. Precipitants include stress and excitement. Idiopathic cyclic vomiting may be a migraine equivalent (abdominal migraine), or it may result from altered intestinal motility or mutations in mitochondrial DNA. The *differential diagnosis* includes gastrointestinal anomalies (malrotation, duplication cysts, choledochal cysts), CNS disorders (neoplasm, epilepsy, vestibular pathology), nephrolithiasis, cholelithiasis, hydronephrosis, metabolic-endocrine disorders (urea cycle, fatty acid metabolism, Addison disease, porphyria, hereditary angioedema, familial Mediterranean fever), chronic appendicitis, and inflammatory bowel disease. Laboratory evaluation is based on a careful history and physical examination and may include, if indicated, endoscopy, contrast gastrointestinal radiography, brain MRI, and metabolic studies (lactate, organic acids, ammonia). *Treatment* includes hydration and ondansetron. *Prevention* may be possible with the antimigraine agent amitriptyline or cyproheptadine.

Diarrhea.

Diarrhea is best defined as excessive loss of fluid and electrolyte in the stool. Normally, a young infant has about 5?g/kg of stool output per day; the volume increases to 200?g/24?hr in an adult. The greatest volume of intestinal water is absorbed in the small bowel; the colon concentrates intestinal contents against a high osmotic gradient. The small intestine of an adult may absorb 10–11?L/day of a combination of ingested and secreted fluid, whereas the colon absorbs about 0.5?L. Disorders that interfere with absorption in the small bowel tend to produce voluminous diarrhea, whereas disorders compromising colonic absorption produce lower volume diarrhea. Dysentery (i.e., small-volume, frequent bloody stools with mucus, tenesmus, and urgency) is the predominant symptom of colitis.

TABLE 287-2 -- **Mechanisms of Diarrhea**

Primary Mechanism	Defect	Stool Examination	Examples	Comment
Secretory	Decreased absorption, ncreased secretion: electrolyte transport	Watery, normal osmolality; osmols = 2 × (Na^+ + K^+)	Cholera, toxigenic *Escherichia coli;* carcinoid, VIP, neuroblastoma, congenital chloride diarrhea, *Clostridium difficile, cryptosporidiosis* (AIDS)	Persists during fasting; bile salt malabsorption also may increase intestinal water secretion; no stool leukocytes
Osmotic	Maldigestion, transport defects, ingestion of unabsorbable solute	Watery, acidic, + reducing substances; increased osmolality; osmosis >2 × (Na^+ + K^+)	Lactase deficiency, glucose-galactose malabsorption, lactulose, laxative abuse	Stops with fasting, increased breath hydrogen with carbohydrate malabsorption, no stool leukocytes
Motility				
Increased motility	Decreased transit time	Loose to normal-appearing stool, stimulated by gastrocolic reflex	Irritable bowel syndrome, thyrotoxicosis, postvagotomy dumping syndrome	Infection also may contribute to increased motility
Decreased motility	Defect in neuromuscular unit(s) Stasis (bacterial overgrowth)	Loose to normal-appearing stool	Pseudo-obstruction, blind loop	Possible bacterial overgrowth
Mucosal inflammation	Inflammation, decreased mucosal surface area and/or colonic reabsorption, increased motility	Blood and increased WBCs in stool	Celiac disease, *Salmonella, Shigella*, amebiasis, *Yersinia, Campylobacter*, rotavirus enteritis	Dysentery = blood, mucus, and WBCs

VIP = vasoactive intestinal peptide; WBC = white blood cell.

Adapted from Behrman RE, Kliegman RM (editors): Nelson Essentials of Pediatrics, 3rd ed. Philadelphia, WB Saunders, 1998.

The basis for all diarrhea is disturbed intestinal solute transport; water movement across intestinal membranes is passive and is determined by both active and passive fluxes of solutes, particularly sodium, chloride, and glucose. The pathogenesis of most episodes of diarrhea can be explained by secretory, osmotic, or motility abnormalities or a combination of these (Table 287–2).

Secretory diarrhea is often caused by a secretagogue, such as cholera toxin, binding to a receptor on the surface epithelium of the bowel and thereby stimulating intracellular accumulation of cyclic adenosine monophosphate or cyclic guanosine monophosphate. Some intraluminal fatty acids and bile salts cause the colonic mucosa to secrete through this mechanism. Diarrhea not associated with an exogenous secretagogue may also have a secretory component (e.g., congenital microvillus inclusion disease). Secretory diarrhea tends to be watery and of large volume; the osmolality of the stool can be accounted for by the presence of electrolytes. Secretory diarrhea generally persists even when no feedings are given by mouth.

Osmotic diarrhea occurs after ingestion of a poorly absorbed solute. The solute may be one that is normally not well absorbed (e.g., magnesium, phosphate, lactulose, or sorbitol) or one that is not well absorbed because of a disorder of the small bowel (e.g., lactose with lactase deficiency or glucose with rotavirus diarrhea). Malabsorbed carbohydrate is fermented in the colon, and short-chain fatty acids (SCFAs) are produced. Although SCFAs can be absorbed in the colon and used as an energy source, the net effect is to increase the osmotic solute load. This form of diarrhea is usually of lesser volume than a secretory diarrhea and stops with fasting. The osmolality of the stool will not be explained by the electrolyte content, because

another osmotic component is present [the difference between electrolyte content (sum of [NA^+], [K^+], and associated anions) and stool osmolality is >50?mOsm] (see Chapter 321). Motility disorders may be associated with rapid or delayed transit and generally are not associated with large volume diarrhea. Slowed motility may be associated with bacterial overgrowth as a cause of diarrhea. The differential diagnosis of common causes of acute and chronic diarrhea is noted in Table 287–3 .

Constipation.

Any definition of constipation is relative and depends on stool consistency, stool frequency, and difficulty in passing the stool. A normal child may have a soft stool only every 2nd or 3rd day without difficulty; this is not constipation. However, a hard stool passed with difficulty every 3rd day should be treated as constipation. Constipation may arise from defects either in filling or emptying the rectum (Box 287–3).

TABLE 287-3 -- Differential Diagnosis of Diarrhea

	Infant	Child	Adolescent
Acute			
Common	Gastroenteritis	Gastroenteritis	Gastroenteritis
	Systemic infection	Food poisoning	Food poisoning
	Antibiotic associated	Systemic infection	Antibiotic associated
		Antibiotic associated	
Rare	Primary disaccharidase deficiency Hirschsprung toxic colitis Adrenogenital syndrome	Toxic ingestion	Hyperthyroidism
Chronic			
Common	Postinfectious secondary lactase deficiency	Postinfectious secondary lactase deficiency	Irritable bowel syndrome
	Cow's milk/soy protein intolerance	Irritable bowel syndrome	Inflammatory bowel disease
	Chronic nonspecific diarrhea of infancy	Celiac disease	Lactose intolerance
	Celiac disease	Lactose intolerance	Giardiasis
	Cystic fibrosis	Giardiasis	Laxative abuse (anorexia nervosa)
	AIDS enteropathy	Inflammatory bowel disease AIDS enteropathy	
Rare	Primary immune defects	Acquired immune defects	Secretory tumor
	Familial villous atrophy	Secretory tumors	Primary bowel tumor
	Secretory tumors	Pseudo-obstruction	Gay bowel disease
	Congenital chloridorrhea	Factitious	
	Acrodermatitis enteropathica		
	Lymphangiectasia		
	Abetalipoproteinemia		
	Eosinophilic gastroenteritis		
	Short bowel syndrome		
	Intractable diarrhea syndrome		
	Autoimmune enteropathy		
	Factitious		
	Microvillus inclusion disease		

From Behrman RE, Kliegman RM (editors): Nelson Essentials of Pediatrics, 3rd ed. Philadelphia, WB Saunders, 1998.

A nursing infant may have very infrequent stools of normal consistency; this is usually a normal pattern. True constipation in the neonatal period is most likely secondary to Hirschsprung disease, intestinal pseudo-obstruction, or hypothyroidism.

Defective rectal filling occurs when colonic peristalsis is ineffective (e.g., in cases of hypothyroidism or opiate use and when bowel obstruction is caused either by a structural anomaly or by Hirschsprung disease). The resultant colonic stasis leads to excessive drying of stool and a failure to initiate reflexes from the rectum that normally trigger evacuation. Emptying the rectum by spontaneous evacuation depends on a defecation reflex initiated by pressure receptors in the rectal muscle. Stool retention, therefore, may also result from lesions involving these rectal muscles, the sacral spinal cord afferent and efferent fibers, or the muscles of the abdomen and pelvic floor. Disorders of anal sphincter relaxation may also contribute to fecal retention.

Constipation tends to be self-perpetuating, whatever its cause. Hard, large stools in the rectum become difficult and even painful to evacuate; thus, more retention occurs and a vicious circle ensues. Distention of the rectum and colon lessens the

sensitivity of the defecation reflex and the effectiveness of peristalsis. Eventually, watery content from the proximal colon may percolate around hard retained stool and pass per rectum unperceived by the child. This involuntary *encopresis* may be mistaken for diarrhea. Constipation does not per se have deleterious systemic organic effects. Urinary tract stasis may accompany severe long-standing cases. Constipation may generate anxiety, having a marked emotional impact on the patient and family.

Abdominal Pain.

Individual children differ greatly in their perception of and tolerance for abdominal pain. This is one reason the evaluation of chronic abdominal pain is difficult. A child with functional abdominal pain (i.e., no identifiable organic cause) may be as uncomfortable as one with an organic cause. This distinction is an extremely important part of the medical evaluation, guiding how the work-up is approached and the child is treated. The more specific the pain and the more suggestive of a particular diagnosis, the more likely it will have an organic basis. Normal growth and physical examination (including a rectal examination) are reassuring in a child who is suspected of having functional pain.

A specific cause may be difficult to find, but the nature and location of a pain-provoking lesion can usually be determined from the clinical description. Two types of nerve fibers transmit painful stimuli in the abdomen. In skin and muscle, A fibers mediate sharp localized pain; and C fibers from viscera, peritoneum, and muscle transmit poorly localized, dull pain. These afferent fibers have cell bodies in the dorsal root ganglia, and some axons cross the midline and ascend to the medulla, midbrain, and thalamus. Pain is perceived in the cortex of the postcentral gyrus, which can receive impulses arising from both sides of the body.

Visceral pain tends to be experienced in the dermatome from which the affected organ receives innervation. Painful stimuli originating in the liver, pancreas, biliary tree, stomach, or upper bowel are felt in the epigastrium; pain from the distal small bowel, cecum, appendix, or proximal colon is felt at the umbilicus; and pain from the distal large bowel, urinary tract, or pelvic organs is usually suprapubic. When pain is referred to remote areas supplied by the same neurologic segment as the diseased organ, the phenomenon usually means an increased intensity of the provoking stimuli. Parietal pain impulses travel in C fibers of nerves corresponding to dermatomes T6–L1; such pain tends to be more localized and intense than visceral pain.

In the gut, the usual stimulus provoking pain is tension or stretching. Inflammatory lesions may lower the pain threshold, but the mechanisms producing pain of inflammation are not clear. Tissue metabolites released near nerve endings probably account for the pain caused by ischemia. Perception of these painful stimuli can be modulated by input from both cerebral and peripheral sources. Psychologic factors are particularly

important. Features of abdominal pain are noted in Tables 287–4 and 287–5 .

Gastrointestinal Hemorrhage.

Bleeding may occur anywhere along the gastrointestinal tract, and identification of the site may be challenging (Table 287–6). The small intestine, which is most difficult to study, is the least likely site of bleeding. The only exception is the painless bleeding of a Meckel diverticulum, which is not difficult to identify. Erosive damage to the mucosa of the gastrointestinal tract is the most common cause of bleeding, although variceal bleeding secondary to portal hypertension occurs frequently enough to require consideration. Vascular malformations are a rare cause in children; they are difficult to identify. The swallowed capsule-size mini camera assists in identifying small vascular lesions.

When bleeding originates in the esophagus, stomach, or duodenum, it may cause *hematemesis*. When exposed to gastric or intestinal juices, blood quickly darkens to resemble coffee grounds; massive bleeding is likely to be red. Red or maroon blood in stools, *hematochezia*, signifies either a distal bleeding site or massive hemorrhage above the distal ileum. Moderate to mild bleeding from sites above the distal ileum tends to cause blackened stools of tarry consistency *(melena);* major hemorrhages in the duodenum or above can cause melena.

Children can develop iron-deficiency anemia from chronic enteric blood loss even when occult blood is not found in stools on random testing. Gastrointestinal hemorrhage may produce hypotension and tachycardia but rarely causes gastrointestinal symptoms; brisk duodenal or gastric bleeding may lead to nausea, vomiting, or diarrhea. The breakdown products of intraluminal blood may tip patients into hepatic coma if liver function is already compromised and lead to elevation of serum bilirubin.

Abdominal Distention and Abdominal Masses.

Enlargement of the abdomen can result from diminished tone of the wall musculature or from increased content: fluid, gas, or solid. Ascites, the accumulation of fluid in the peritoneal cavity, distends the abdomen both in the flanks and anteriorly when it is large in volume. This fluid shifts with movement of the patient and conducts a

percussion wave.

Ascitic fluid is usually a transudate with a low-protein concentration resulting from reduced plasma colloid osmotic pressure of hypoalbuminemia, from raised portal venous pressure, or from both. In cases of portal hypertension, the fluid leak probably occurs from lymphatics on the liver surface and from

TABLE 287-4 -- **Recurrent Abdominal Pain in Children**

Disorder	Characteristics	Key Evaluations
Nonorganic		
Recurrent abdominal pain syndrome (functional abdominal pain)	Nonspecific pain, often periumbilical	Hx and PE; tests as indicated
Irritable bowel syndrome	Intermittent cramps, diarrhea, and constipation	Hx and PE
Nonulcer dyspepsia	Peptic ulcer–like symptoms without abnormalities on evaluation of the upper gastrointestinal tract	Hx; esophagogastroduodenoscopy
Gastrointestinal Tract		
Chronic constipation	Hx of stool retention, evidence of constipation on examination	Hx and PE; plain x-ray of abdomen
Lactose intolerance	Symptoms may be associated with lactose ingestion; bloating, gas, cramps, and diarrhea	Trial of lactose-free diet; lactose breath hydrogen test
Parasite infection (especially *Giardia*)	Bloating, gas, cramps, and diarrhea	Stool evaluation for O & P; specific immunoassays for *Giardia*
Excess fructose or sorbitol ingestion	Nonspecific abdominal pain, bloating, gas, and diarrhea	Large intake of apples, fruit juice, or candy/chewing gum sweetened with sorbitol
Crohn disease	See Chapter 317	
Peptic ulcer	Burning or gnawing epigastric pain; worse on awakening or before meals; relieved with antacids	Esophagogastroduodenoscopy or upper GI contrast x-rays
Esophagitis	Epigastric pain with substernal burning	Esophagogastroduodenoscopy
Meckel's diverticulum	Periumbilical or lower abdominal pain; may have blood in stool	Meckel scan or enteroclysis
Recurrent intussusception	Paroxysmal severe cramping abdominal pain; blood may be present in stool with episode	Identify intussusception during episode or lead point in intestine between episodes with contrast studies of gastrointestinal tract
Internal, inguinal, or abdominal wall hernia	Dull abdomen or abdominal wall pain	PE, CT of abdominal wall
Chronic appendicitis or appendiceal mucocele	Recurrent RLQ pain; often incorrectly diagnosed, may be rare cause of abdominal pain	Barium enema, CT
Gallbladder and Pancreas		
Cholelithiasis	RUQ pain, may worsen with meals	Ultrasound of gallbladder
Choledochal cyst	RUQ pain, mass ± elevated bilirubin	Ultrasound or CT of RUQ
Recurrent pancreatitis	Persistent boring pain, may radiate to back, vomiting	Serum amylase and lipase ± serum trypsinogen; ultrasound or CT of pancreas
Genitourinary Tract		
Urinary tract infection	Dull suprapubic pain, flank pain	Urinalysis and urine culture; renal scan
Hydronephrosis	Unilateral abdominal or flank pain	Ultrasound of kidneys
Urolithiasis	Progressive, severe pain: flank to inguinal region to testicle	Urinalysis, ultrasound, IVP, CT
Other genitourinary disorders	Suprapubic or lower abdominal pain; genitourinary symptoms	Ultrasound of kidneys and pelvis; gynecologic evaluation
Miscellaneous Causes		
Abdominal migraine	See text; nausea, family Hx migraine	Hx
Abdominal epilepsy	May have seizure prodrome	EEG (may require more than one study, including sleep-deprived EEG)

Gilbert syndrome	Mild abdominal pain (causal or coincidental?); slightly elevated unconjugated bilirubin	Serum bilirubin
Familial Mediterranean fever	Paroxysmal episodes of fever, severe abdominal pain, and tenderness with other evidence of polyserositis	Hx and PE during an episode, DNA diagnosis
Sickle cell crisis	Anemia	Hematologic evaluation
Lead poisoning	Vague abdominal pain ± constipation	Serum lead level
Henoch-Schönlein purpura	Recurrent, severe crampy abdominal pain, occult blood in stool, characteristic rash, arthritis	Hx, PE, urinalysis
Angioneurotic edema	Swelling of face or airway, crampy pain	Hx, PE, upper gastrointestinal contrast x-rays, serum C1 esterase inhibitor
Acute intermittent porphyria	Severe pain precipitated by drugs, fasting, or infections	Spot urine for porphyrins

O & P = ova and parasites; Hx = history; PE = physical exam; RUQ = right upper quadrant; RLQ = right lower quadrant; IVP = intravenous pyelography; EEG = electroencephalogram; abd = abdominal.

TABLE 287-5 -- Distinguishing Features of Acute Gastrointestinal Tract Pain in Children

Disease	Onset	Location	Referral	Quality	Comments
Pancreatitis	Acute	Epigastric, left upper quadrant	Back	Constant, sharp, boring	Nausea, emesis, tenderness
Intestinal obstruction	Acute or gradual	Periumbilical—lower abdomen	Back	Alternating cramping (colic) and painless periods	Distention, obstipation, emesis, increased bowel sounds
Appendicitis	Acute	Periumbilical, then localized to lower right quadrant; generalized with peritonitis	Back or pelvis if retrocecal	Sharp, steady	Anorexia, nausea, emesis, local tenderness, fever with peritonitis
Intussusception	Acute	Periumbilical—lower abdomen	None	Cramping, with painless periods	Hematochezia, knees in pulled-up position
Urolithiasis	Acute, sudden	Back (unilateral)	Groin	Sharp, intermittent, cramping	Hematuria
Urinary tract infection	Acute, sudden	Back	Bladder	Dull to sharp	Fever, costochondral tenderness, dysuria, urinary frequency

	Coagulopathy	

visceral peritoneal capillaries, but ascites does not usually develop until the serum albumin level falls. Sodium excretion in the urine decreases greatly as the ascitic fluid accumulates, and thus additional dietary sodium goes directly to the peritoneal space, taking with it more water. When ascitic fluid contains a high protein concentration, it is usually an exudate caused by an inflammatory or neoplastic lesion.

When fluid distends the gut, either obstruction or imbalance between absorption and secretion should be suspected. The factors causing fluid accumulation in the bowel lumen frequently cause gas to accumulate, too. The result may be audible gurgling noises. The source of gas is usually swallowed air, but endogenous flora may increase considerably in malabsorptive states and produce excessive gas when substrate reaches the lower intestine. Gas in the peritoneal cavity (pneumoperitoneum), perhaps signaled by a tympanitic percussion note even over solid organs such as the liver, indicates a perforated viscus.

An abdominal organ may enlarge diffusely or be affected by a discrete mass. In the digestive tract, such discrete masses may occur in the lumen, in the wall, or in the mesentery. In a constipated child, mobile, nontender fecal masses are often found. Anomalies, cysts, or inflammatory disease can affect the wall of the gut; gut wall neoplasms are extremely rare in children. The liver may enlarge diffusely in response to many disorders. Discrete liver masses may be islands of regenerating liver tissue in a cirrhotic liver or may be inflammatory or neoplastic in origin.

Section 2 - *The Oral Cavity*

Norman Tinanoff

Oral health is integral to the physical and psychologic health of children. Timely diagnosis and treatment require close cooperation between physicians and dentists. Disorders of the teeth and surrounding structures may occur in isolation or in combination with other systemic conditions. Dental caries is the most common chronic disease of childhood, and children identified at high risk for caries should be referred for dental care by 1 yr of age. Approximately 10% of children sustain significant trauma to their teeth.

Chapter 288 - Development and Developmental Anomalies of the Teeth

INITIATION

The primary teeth form in dental crypts that arise from a band of epithelial cells incorporated into each developing jaw. By the 12th wk of fetal life, each of these epithelial bands (the dental laminae) has five areas of rapid growth on each side of the maxilla and the mandible, seen as rounded, budlike enlargements. Organization of adjacent mesenchyme takes place in each area of epithelial growth, and the two elements together are the beginning of a tooth.

After the formation of these crypts for the 20 primary teeth, another generation of tooth buds forms lingually (toward the tongue), which will develop into the succeeding permanent incisors, canines, and premolars that eventually replace the primary teeth. This process takes place from about the 5th gestational month for the central incisors to about the 10th mo of age for the second premolars. The permanent first, second, and third molars, on the other hand, arise from extension of the dental laminae distal to the second primary molars. Buds for these teeth develop at approximately 4 mo of gestation, 1 yr of age, and 4 to 5 yr of age, respectively.

Histodifferentiation-Morphodifferentiation.

As the epithelial bud proliferates, the deeper surface invaginates and a mass of mesenchyme becomes partially enclosed. The epithelial cells differentiate into the ameloblasts that lay down an organic matrix that forms enamel; the mesenchyme forms the dentin and dental pulp.

Calcification.

After the organic matrix has been laid down, the deposition of the inorganic mineral crystals takes place from

---

several sites of calcification that later coalesce. The characteristics of the inorganic portions of a tooth can be altered by (1) disturbances in formation of the matrix, (2) decreased availability of minerals, or (3) the incorporation of foreign materials. Such disturbances may affect the color, texture, or thickness of the tooth surface. Calcification of primary teeth begins at 3 to 4 mo in utero and concludes postnatally at approximately 12 mo with mineralization of the second primary molars (Table 288–1).

Eruption.

At the time of tooth bud formation, each tooth begins a continuous movement toward the oral cavity. The times of eruption of the primary and permanent teeth are listed in Table 288–1 .

ANOMALIES ASSOCIATED WITH TOOTH DEVELOPMENT

Both failures and excesses of tooth initiation are observed. *Developmentally missing teeth* may result from environmental insult, a genetic defect involving only teeth, or the manifestation of a syndrome. *Anodontia*, or absence of teeth, occurs when no tooth buds form (ectodermal dysplasia, or familial missing teeth) or when there is a disturbance of a normal site of initiation (the area of a palatal cleft). The teeth that are most commonly absent include the third molars, the maxillary lateral incisors, and the mandibular second premolars.

If the dental lamina produces more than the normal number of buds, supernumerary teeth occur, most often in the area between the maxillary central incisors. Because they

Modified from Logan WHG, Kronfeld R: Development of the human jaws and surrounding structures from birth to age fifteen years. J Am Dent Assoc 1993;20:379.

tend to disrupt the position and eruption of the adjacent normal teeth, their identification by radiographic examination is important. Supernumerary teeth also occur with cleidocranial dysplasia (see Chapter 292) and in the area of cleft palates.

Twinning, in which two teeth are joined together, is most often observed in the mandibular incisors of the primary dentition. It may result from gemination, fusion, or concrescence. Gemination is the result of the division of one tooth germ to form a bifid crown on a single root with a common pulp canal; an extra tooth appears to be present in the dental arch. Fusion is the joining of incompletely developed teeth that, owing to pressure or trauma or crowding, continue to develop as one tooth. Fused teeth are sometimes joined through their entire length; in other cases, a single wide crown is supported on two roots. Concrescence is the attachment of the roots of closely approximated adjacent teeth by an excessive deposit of cementum. This type of twinning, unlike the others, is found most often in the maxillary molar region.

Disturbances during differentiation may result in alterations in dental morphology, such as *macrodontia* (large teeth) or *microdontia* (small teeth). The maxillary lateral incisors may assume a slender, tapering shape ("peg-shaped laterals").

Amelogenesis imperfecta represents a group of hereditary conditions that manifest in enamel defects of the primary and permanent teeth without evidence of systemic disorders. The teeth are covered by only a thin layer of abnormally formed enamel through which the yellow underlying dentin is seen. The primary teeth are generally affected more than the permanent teeth. Susceptibility to caries is low, but the enamel is subject to destruction from abrasion. Complete coverage of the crown may be indicated for dentin protection, to reduce tooth sensitivity, and for improved appearance.

Dentinogenesis imperfecta, or hereditary opalescent dentin, is an analogous condition to amelogenesis imperfecta in which the odontoblasts fail to differentiate

normally, resulting in poorly calcified dentin. This autosomal dominant disorder may also occur in patients with osteogenesis imperfecta. The enamel-dentin junction is altered, causing enamel to break away. The exposed dentin is then susceptible to abrasion, in some cases worn to the gingiva. The teeth are opaque and pearly, and the pulp chambers are generally obliterated by calcification. Both primary and permanent teeth are usually involved.

Localized disturbances of calcification that correlate with periods of illness, malnutrition, premature birth, or birth trauma are common. Hypocalcification appears as opaque white patches or horizontal lines on the tooth; hypoplasia is more severe and manifests as pitting or areas devoid of enamel. Systemic conditions, such as renal failure and cystic fibrosis, are associated with enamel defects. Local trauma to the primary incisors also can affect calcification of permanent incisors.

Fluorosis (mottled enamel) may result from systemic fluoride consumption above 0.05?mg/kg/day during enamel formation. This high fluoride consumption may be caused by residing in an area of high fluoride content of the drinking water (greater than 2.0?ppm), swallowing excessive fluoridated toothpaste, or inappropriate fluoride prescriptions. Excessive fluoride during enamel formation affects ameloblastic function, resulting in inconspicuous white, lacy patches on the enamel to severe, brownish discoloration and hypoplasia. The latter changes are usually seen with fluoride concentrations in the drinking water greater than 5.0?ppm.

Discolored teeth may result from incorporation of foreign substances into developing enamel. Neonatal *hyperbilirubinemia* may produce blue to black discoloration of the primary teeth. Porphyria produces a red-brown discoloration. *Tetracyclines* are extensively incorporated into bones and teeth and, if administered during the period of formation of enamel, may result

in brown-yellow discoloration and hypoplasia of the enamel. Such teeth fluoresce under ultraviolet light. The period at risk extends from about the 4th mo of gestation to the 7th yr of life. Repeated or prolonged therapy with tetracycline carries the highest risk.

Delayed eruption of the 20 primary teeth may be familial or indicate systemic or nutritional disturbances such as hypopituitarism, hypothyroidism, cleidocranial dysplasia, trisomy 21, progeria, Albright osteodystrophy, incontinentia pigmenti, rickets, or multiple syndromes. Failure of eruption of single or small groups of teeth may arise from local causes such as malpositioned teeth, supernumerary teeth, cysts, or retained primary teeth. Premature loss of primary teeth is most commonly caused by premature eruption of the permanent teeth. If the entire dentition is advanced for age and sex, precocious puberty or hyperthyroidism should be considered.

Natal teeth are observed in approximately 1 in 2,000 newborn infants; usually there are two in the position of the mandibular central incisors. Natal teeth are present at birth, whereas neonatal teeth erupt in the 1st mo of life. Attachment of natal/neonatal teeth is generally limited to the gingival margin, with little root formation or bony support. They may be a supernumerary or a prematurely erupted primary tooth. A radiograph can easily differentiate between the two conditions. Natal teeth are associated with cleft palate, Pierre Robin syndrome, Ellis-van Creveld syndrome, Hallermann-Streiff syndrome, pachyonychia congenita, and other anomalies. A family history of natal teeth or premature eruption is present in 15–20% of affected children.

Natal/neonatal teeth may occasionally result in pain and refusal to feed and at times may produce maternal discomfort because of abrasion or biting of the nipple during nursing. There is a remote danger of detachment, with aspiration of the tooth. Because the tongue lies between the alveolar processes during birth, it may become lacerated, and occasionally the tip is amputated (Riga-Fede disease). Decisions regarding extraction of prematurely erupted primary teeth must be made on an individual basis.

Exfoliation failure occurs when a primary tooth is not shed before the eruption of its permanent successor. Most often the primary tooth will eventually exfoliate, but in some cases the primary tooth may need to be extracted. This occurs most commonly in the mandibular incisor region.

Chapter 289 - Disorders of the Oral Cavity Associated with Other Conditions

Disorders of the teeth and surrounding structures may occur in isolation or in combination with other systemic conditions. Most commonly, medical conditions that occur during tooth development may affect tooth formation or appearance. Damage to teeth during their development is permanent. Some of the disorders of the oral cavity associated with medical conditions are noted in Table 289–1 .

TABLE 289-1 -- **Dental Problems Associated with Selected Medical Conditions**

Medical Condition	Common Associated Dental or Oral Findings
Cleft lip and palate	Missing teeth, extra supernumerary) teeth, shifting of arch segments, feeding difficulties, speech problems
Kidney failure	Mottled enamel (permanent teeth), facial dysmorphology
Cystic fibrosis	Stained teeth with extensive medication, mottled enamel
Immunosuppression	Oral candidiasis with potential for systemic candidiasis, cyclosporine-induced gingival hyperplasia
Low birthweight with prolonged oral intubation	Palatal groove, narrow arch
Heart defects with susceptibility for bacterial endocarditis	Bacteremia from dental procedures or trauma
Neutrophil chemotactic deficiency	Juvenile periodontitis (loss of supporting bone around teeth)
Juvenile diabetes (uncontrolled)	Juvenile periodontitis
Neuromotor dysfunction	Oral trauma from falling; malocclusion (open bite); gingivitis from lack of hygiene
Prolonged illness (generalized) during tooth formation	Enamel hypoplasia of crown portions forming during illness
Seizures	Gingival enlargement if phenytoin is used
Maternal infections	Syphilis—abnormally shaped teeth
Vitamin D–dependent rickets	Enamel hypoplasia

Chapter 290 - Malocclusion

The oral cavity is essentially a masticatory instrument. The purpose of the anterior teeth is to bite off portions of large food. The posterior teeth reduce foodstuffs to a soft, moist bolus. The cheeks and tongue force the food onto the areas of tooth contact. Establishing a proper relationship between the mandibular and maxillary teeth is important for physiologic and cosmetic reasons.

Variations in Growth Patterns.

Growth patterns are classified into three main types of occlusion, determined when the jaws are closed and the teeth are held together (Fig. 290–1). According to the Angle Classification of Malocclusion, in Class I (normal) the cusps of the posterior mandibular teeth interdigitate ahead of and inside the corresponding cusps of the opposing maxillary teeth. This relationship provides a normal facial profile. In Class II malocclusion, "buck teeth," the cusps of the posterior mandibular teeth are behind and inside the corresponding cusps of the maxillary teeth. This common occlusal disharmony is found in approximately 45% of the population. The facial profile may give the appearance of a "receding chin" (retrognathia) or protruding front teeth. The resultant increased space between upper and lower anterior teeth encourages finger sucking and tongue-thrust habits. Additionally, children with pronounced Class II malocclusions are at greater risk of damage to the incisors due to trauma. In Class III malocclusion, "underbite," the cusps of the posterior mandibular teeth interdigitate a tooth or more ahead of their opposing maxillary counterparts. The anterior teeth appear in "cross bite," with the mandibular incisors protruding beyond the maxillary incisors. The facial profile gives the appearance of a "protruding chin" (prognathia).

Figure 290-1 Angle classification of occlusion. The typical correspondence between the facial-jaw profile and molar relationship is shown.

Cross Bite.

Normally, the mandibular teeth are in a position just inside the maxillary teeth, so that the outside mandibular cusps or incisal edges meet the central portion of the opposing maxillary teeth. A reversal of this relation is referred to as a *cross bite*. Cross bites may be anterior, involving the incisors; may be posterior, involving the molars; or may involve single or multiple teeth.

Open and Closed Bites.

If the posterior mandibular and maxillary teeth make contact with each other but the anterior teeth are still apart, the condition is called an *open bite*. Open bites may be due to skeletal growth pattern or digit sucking. If digit sucking is terminated before skeletal and dental growth is complete, natural resolution of the open bite may occur. If mandibular anterior teeth occlude inside the maxillary anterior teeth in an over-closed position, the condition is referred to as a *closed or deep bite*. Treatment of open and closed bites consists of orthodontic correction, generally performed in the preteen or teenage years. Some cases require orthognathic surgery to optimally position the jaws in a vertical direction.

Dental Crowding.

Overlap of incisors can result when the jaws are too small or the teeth are too large for adequate alignment of the teeth. Growth of the jaws is mostly in the posterior aspects of the mandible and maxilla, and therefore inadequate space for the teeth at 7 or 8 yr of age will not resolve with growth of the jaws. Spacing in the primary dentition is normal and favorable for adequate alignment of successor teeth.

Digit Sucking.

Various and conflicting etiologic theories and recommendations for correction have been proposed for digit sucking in children. Prolonged digit sucking can cause flaring of the maxillary incisor teeth, an open bite, as well as a posterior cross bite. The prevalence of digit sucking decreases steadily from the age of 2 yr to approximately 10% by the age of 5. The earlier the habit is discontinued after the eruption of the permanent maxillary incisors (age 7–8 yr), the greater the likelihood that there will be lessening effects on the dentition. A variety of treatments have been suggested, from behavioral modification to insertion of an appliance with extensions that serves as a reminder when the child attempts to insert the digit. The greatest likelihood of success occurs in cases in which the child desires to stop. Stopping of the habit, however, will not rectify a malocclusion caused by a deviant growth pattern.

Chapter 291 - Cleft Lip and Palate

Clefts of the lip and palate are distinct entities closely related embryologically, functionally, and genetically. Although there are a variety of theories, it is commonly thought that cleft of the lip appears because of hypoplasia of the mesenchymal layer, resulting in a failure of the medial nasal and maxillary processes to join. Cleft of the palate appears to represent failure of the palatal shelves to approximate or fuse.

Incidence and Epidemiology.

The incidence of cleft lip with or without cleft palate is about 1 in 750 white births; the incidence of cleft palate alone is about 1 in 2,500 white births. Clefts of the lip are more common in males. Possible causes include maternal drug exposure, a syndrome-malformation complex, or genetic factors. Although both may appear to occur sporadically, the presence of susceptibility genes appears important. There are families in which a cleft lip or palate, or both, is inherited in a dominant fashion (van der Woude syndrome), and careful examination of parents is important to distinguish this type from others, because the recurrence risk is 50%. Ethnic factors also affect the incidence of cleft lip and palate. Clefts are highest among Asians and lowest among blacks. The incidence of associated congenital malformations and of impairment in development is increased in children with cleft defects, especially in those with cleft palate alone. These findings are partially explained by an increased incidence of conductive hearing impairment in children with cleft palate, owing in part to repeated middle ear infections, and by the increased frequency of cleft defects among children with chromosomal abnormalities. The risks of recurrence of cleft defects within families are discussed in Chapters 69 and 72 .

Clinical Manifestations.

Cleft lip may vary from a small notch in the vermilion border to a complete separation extending into the floor of the nose. Clefts may be unilateral (more often on the left side) or bilateral and may involve the alveolar ridge. Deformed, supernumerary, or absent teeth are associated findings. The nasal alar cartilage clefts of the lip are frequently associated with deficiency of the columella and elongation of the vomer, producing a protrusion of the anterior aspect of the cleft premaxillary process.

Isolated cleft palate occurs in the midline and may involve only the uvula or may extend into or through the soft and hard palates to the incisive foramen. When associated with cleft lip, the defect may involve the midline of the soft palate and extend into the hard palate on one or both sides, exposing one or both of the nasal cavities as a unilateral or bilateral cleft palate.

Treatment.

A complete program of habilitation for the child with a cleft lip or palate may require years of special treatment by a team consisting of a pediatrician, plastic surgeon, otolaryngologist, pediatric dentist, prosthodontist, orthodontist, speech therapist, geneticist, medical social worker, psychologist, and public health nurse. The child's physician should be responsible for seeking the coordinated use of specialists and for parental counseling and guidance.

The immediate problem in an infant born with a cleft lip or palate is feeding. Although some may advocate the construction of a plastic obturator to assist in feedings, most believe that with the use of soft artificial nipples with large openings, a squeezable bottle, and proper instruction, feeding of infants with clefts can be achieved with relative ease and effectiveness.

Surgical closure of a cleft lip is usually performed by 3 mo of age, when the infant has shown satisfactory weight gain and is free of any oral, respiratory, or systemic infection. Z-plasty is the most commonly used technique; a staggered suture line minimizes notching of the lip from retraction of scar tissue. The initial repair may be revised at 4 or 5 yr of age. Corrective surgery on the nose may be delayed until adolescence. Nasal surgery can also be performed at the time of the lip repair. Cosmetic results depend on the extent of the original deformity, healing potential of the individual, absence of infection, and the skill of the surgeon.

Because clefts of the palate vary considerably in size, shape, and degree of deformity, the timing of surgical correction should be individualized. Criteria such as width of the cleft, adequacy of the existing palatal segments, morphology of the surrounding areas (e.g., width of the oropharynx), and neuromuscular function of the soft palate and pharyngeal walls affect the decision. The goals of surgery are the union of the cleft segments, intelligible and pleasant speech, reduction of nasal regurgitation, and avoidance of injury to the growing maxilla.

In an otherwise healthy child, closure of the palate is usually done before 1 yr of age to enhance normal speech development. When surgical correction is delayed beyond the 3rd yr, a contoured speech bulb can be attached to the posterior of a maxillary denture so that contraction of the pharyngeal and velopharyngeal muscles can bring tissues into contact with the bulb to accomplish occlusion of the nasopharynx and help the child develop intelligible speech.

A cleft palate usually crosses the alveolar ridge and interferes with the formation of teeth in the maxillary anterior region. Teeth in the cleft area may be displaced, malformed, or missing. Missing teeth or teeth that are nonfunctional are replaced by prosthetic devices.

Postoperative Management.

During the immediate postoperative period, special nursing care is essential. Gentle

aspiration of the nasopharynx minimizes the chances of the common complications of atelectasis or pneumonia. The primary considerations in postoperative care are maintenance of a clean suture line and avoidance of tension on the sutures. For these reasons, the infant is fed with a Mead Johnson bottle and the arms are restrained with elbow cuffs. A fluid or semifluid diet is maintained for 3 wk; feeding is continued with a Mead Johnson bottle or a cup. The patient's hands, toys, and other foreign bodies must be kept away from the surgical site.

Sequelae of Cleft Lip and Palate.

Recurrent otitis media and hearing loss are frequent with cleft palate. Displacement of the maxillary arches and malposition of the teeth usually require orthodontic correction.

Speech defects are often associated with cleft lip and palate and may be present or persist because of inadequate surgical closure of the palate. Such speech is characterized by the emission of air from the nose and by a hypernasal quality with certain sounds. Both before and sometimes after palatal surgery, the speech defect is caused by inadequacies in function of the palatal and pharyngeal muscles. The muscles of the soft palate and the lateral and posterior walls of the nasopharynx constitute a valve that separates the nasopharynx from the oropharynx during swallowing and in the production of certain sounds. If the valve does not function adequately, it is difficult to build up enough pressure in the mouth to make such explosive sounds as *p, b, d, t, h, y*, or the sibilants *s, sh*, and *ch*, and such words as "cats," "boats," and "sisters" are not intelligible. After operation or the insertion of a speech appliance, speech therapy is necessary.

Palatopharyngeal Incompetence.

The speech disturbance characteristic of the child with a cleft palate can also be produced by other osseous or neuromuscular abnormalities where there is an inability to form an effective seal between oropharynx and nasopharynx during swallowing or phonation. The abnormality may be in the structure of the palate or pharynx or in the muscles attached to these structures. In a child who has the potential for abnormal speech, adenoidectomy may precipitate overt hypernasality. A submucous cleft palate may be the cause of this problem. In such cases, the adenoid mass may have facilitated velopharyngeal closure when the elevated soft palate contacted it. If the neuromuscular function is adequate, compensation in palatopharyngeal movement may take place and the speech defect may improve, although speech therapy is necessary. In other cases, slow involution of the adenoids may allow for gradual compensation in palatal and pharyngeal muscular function. This may explain why a speech defect does not become apparent in some children who have a submucous cleft palate or similar anomaly predisposing to palatopharyngeal incompetence. Velopharyngeal incompetency (VPI) can also occur in children with an inherent palatal abnormality (velocardiofacial syndrome). VPI should be evaluated by a craniofacial disorders team or a geneticist.

CLINICAL MANIFESTATIONS.

Although clinical signs vary, the symptoms of palatopharyngeal incompetence are similar to those of a cleft palate. There may be hypernasal speech (especially noted in the articulation of pressure consonants such as *p, b, d, t, h, v, f*, and *s*); conspicuous constricting movement of the nares during speech; inability to whistle, gargle, blow out a candle, or inflate a balloon; loss of liquid through the nose when drinking with the head down; otitis media; and hearing loss. Oral inspection may reveal a cleft palate or a relatively short palate with a large oropharynx; absent, grossly asymmetric, or minimal muscular activity of the soft palate and pharynx during phonation or gagging; or a submucous cleft. The latter is suggested by a bifid uvula, by a translucent membrane in the midline of the soft palate (revealing lack of continuity of muscles), by palpable notching in the posterior border of the hard palate instead of a posterior nasal spinous process, or by forward or V-shaped displacement or grooving on the soft palate during phonation or gagging.

Palatopharyngeal incompetence may also be demonstrated radiographically. The head should be carefully positioned to obtain a true lateral view; one film is obtained with the patient at rest and another during continuous phonation of the vowel *u* as in "boom." The soft palate contacts the posterior pharyngeal wall in normal function, whereas in palatopharyngeal incompetence such contact is absent. Most accurate evaluations of VPI are accomplished by the use of nasoendoscopy.

TREATMENT.

In selected cases, the palate may be retropositioned or pharyngoplasty performed using a flap of tissue from the posterior pharyngeal wall. Dental speech appliances have also been used successfully. The type of surgery used is best tailored to the findings on nasoendoscopy.

Chapter 292 - Syndromes with Oral Manifestations

Many syndromes have distinct or accompanying facial, oral, and dental manifestations (e.g., Apert syndrome, see Chapter 585 ; Crouzon disease, see Chapter 585 ; Down syndrome, see Chapter 70). The conditions described here are examples of some of the common occurring conditions.

Osteogenesis imperfecta often is accompanied by effects on the teeth, termed *dentinogenesis imperfecta* (see Chapter 288). Depending on the severity of presentation, treatment of the dentition varies from routine preventive and restorative monitoring to covering affected posterior teeth with stainless steel crowns, to reduce abrasion from chewing. Dentinogenesis imperfecta can also occur in isolation without the bony effects.

Another syndrome, *cleidocranial dysplasia*, has orofacial variations such as frontal bossing, mandibular prognathism, and a broad nasal base. Tooth eruption is often delayed. In addition, the primary teeth can be abnormally retained while the permanent teeth remain unerupted. Supernumerary teeth are common, especially in the premolar area. Although the erupted teeth are usually free of hypoplasia, variations in the size and shape of the teeth are common. Restoration of the erupted primary and permanent teeth should be performed when carious lesions are present. It is common to see extensive dental rehabilitation therapy in individuals with this disorder to maintain effective mastication.

Ectodermal dysplasia (see Chapter 639) is a heterogeneous group of conditions in which oral manifestations range from little or no involvement (the dentition is completely normal) to cases in which the teeth can be totally or partially absent or malformed. Because alveolar bone does not develop in the absence of teeth, the alveolar processes can be either totally or partially absent, and the resultant overclosure of the mandible causes the lips to protrude. Facial development is otherwise not disturbed. Teeth, when present, can range from normal to small and conical. If aplasia of the buccal and labial mucous glands is present, dryness and irritation of the oral mucosa can occur. People with ectodermal dysplasia may need either partial or full dentures, even at a very young age. The vertical height between the jaws is thus restored, improving the position of the lips and facial contours. Masticatory function is restored, and eating habits are therefore improved.

Pierre Robin sequence consists of micrognathia usually accompanied by a high arched or cleft palate. The tongue is usually of normal size, but the floor of the mouth is foreshortened. Obstruction of the air passages may occur, particularly on inspiration, and usually requires treatment to prevent suffocation. The infant should be maintained in a prone or partially prone position so that the tongue falls forward to relieve respiratory obstruction. Some patients may require endotracheal intubation or tracheostomy. Sufficient mandibular growth often takes place within a few months to relieve the potential airway obstruction. Often the growth of the mandible will achieve a normal profile within 4–6 yr. The feeding of infants with mandibular hypoplasia requires great care and patience but can usually be accomplished without resorting to gavage. Dental anomalies usually require individualized treatment. Thirty to 50 per cent of children with Pierre Robin syndrome have Stickler syndrome, an autosomal dominant condition that includes other findings such as early arthritis and ocular problems.

In *mandibulofacial dysostosis* (Treacher Collins syndrome or Franceschetti syndrome), the facial appearance is characterized by downward sloping palpebral fissures, colobomas of the lower eyelids, sunken cheekbones, blind fistulas opening between the angles of the mouth and the ears, deformed pinnae, atypical hair growth extending toward the cheeks, receding chin, and large mouth. Facial clefts, abnormalities of the ears, and deafness are common. The disorder is autosomal dominant, often with incomplete penetrance. The mandible is usually hypoplastic; the ramus may be deficient, and the coronoid and condylar processes are flat or even aplastic. The palatal vault may be either high or cleft. Infrequently, unilateral or bilateral macrostomia, or failure of embryonic fusion of the maxillary and mandibular processes, may occur. Dental malocclusions are frequent. The teeth may be widely separated, hypoplastic, or displaced or have an open bite. Orthodontic and routine dental treatments are indicated.

Hemifacial microsomia is usually characterized by unilateral hypoplasia of the mandible and can be associated with partial paralysis of the facial nerve, macrostomia, blind fistulas between the angles of the mouth and the ears, and deformed external ears. Severe facial asymmetry and malocclusion can develop because of the absence or hypoplasia of the mandibular condyle on the affected side. Congenital condylar deformity tends to increase with age. Early craniofacial surgery may be indicated to minimize the deformity. This disorder can be associated with ocular and vertebral anomalies (oculo-auriculo-vertebral spectrum, including Goldenhar syndrome); therefore, radiographs of the vertebrae and ribs should be considered to determine the extent of skeletal involvement.

Chapter 293 - Dental Caries

Etiology.

The development of dental caries depends on interrelationships between the tooth surface, dietary carbohydrates, and specific oral bacteria. Organic acids produced by bacterial fermentation of dietary carbohydrates reduce the pH of dental plaque adjacent to the tooth to a point at which demineralization occurs. The initial carious lesion appears as an opaque white spot on the enamel; and with progressive loss of tooth mineral, cavitation occurs.

A group of microorganisms, *mutans streptococci*, are associated with the development of dental caries. These bacteria have the ability to adhere to enamel, produce abundant acid, and survive at low pH. Once the enamel surface cavitates, other oral bacteria (lactobacilli) colonize the tooth, produce acid, and foster further tooth demineralization. Demineralization from bacterial acid production is determined by the frequency of carbohydrate consumption and by the type of carbohydrate. Sucrose is the most cariogenic sugar because one of its by-products during bacterial metabolism is glucan, a polymer that enables bacteria to adhere more readily to tooth structures. With regard to frequency of consumption, the cariogenic potential of a nursing bottle of a sweetened beverage that is consumed throughout the night or at nap times is much greater than that of the same volume of drink consumed at a single meal. Similarly, sticky candies retained orally for long periods (sucrose in sticky candies) is more cariogenic than the sugar in food products retained for short times.

Epidemiology.

The incidence of dental caries has decreased in developed countries in the past 30 yr but still remains highly prevalent in low-income children and children from developing countries. The decrease is thought to be due to advances in

prevention, particularly in the use of fluorides. Still, over half of the children in the United States have dental caries, with most of those having caries primarily in the pits and fissures of the occlusal (biting) surfaces of the molar teeth.

Clinical Manifestations.

The age-related epidemiology is noted in Figure 293–1 . Dental caries of the primary dentition usually begin in the pits and fissures. Small lesions may be difficult to diagnose by visual inspection, but larger lesions present as cavitations of the occlusal surface. The second most frequent sites of caries occur on approximal sites (contact surfaces between the teeth), which in many cases can only be detected by intraoral radiographs. Caries lesions of the exposed smooth (buccal and lingual) surfaces are generally found only in children with rampant caries (Fig. 293–2).

Rampant caries in infants and toddlers, referred to as early childhood caries (ECC), nursing bottle caries, or baby bottle tooth decay, was ascribed to inappropriate bottle-feeding. Although the combination of a child infected with cariogenic bacteria and the frequent ingestion of sugar, either in the bottle or in solid foods, is critical, other factors such as enamel hypoplasia of primary teeth because of nutritional deficiencies during pregnancy or because of premature birth may play a role. Reports have also associated “at will” breast-feeding in older infants with caries of the maxillary anterior teeth, but the possibility of cariogenic dietary practices other than breast-feeding, in such cases, needs further exploration.

Early childhood caries are common, with a reported prevalence of 30–50% in children from low socioeconomic backgrounds and as high as 70% in some Native American groups. It may occur as early as 12 mo of age, long before children visit a dentist. Pediatricians have the responsibility to both examine the child's teeth for caries and to refer to a dentist those children who they consider at risk for ECC. Risk factors include high-frequency sugar consumption (prolonged and frequent drinking from bottle or sippy cup, frequent eating of sugar-containing snacks); children of low socioeconomic status; immigrant children; parents or siblings with high caries rates; and evidence of defects on the teeth.

Figure 293-1 Schematic for different kinds of caries and ages when each can start. A significant percentage of children remain caries free. Nursing caries (early childhood caries [ECC]) begins between 1 and 2 yr of age; children with ECC are at significantly greater risk for future caries than are cariesfree children. Pit and fissure caries usually begins after about age 3, with caries of approximating tooth surfaces beginning shortly after. (From Johnsen DC: The role of the pediatrician in identifying and treating dental caries. *Pediatr Clin North Am* 1991;38: 1173.)

Children who develop caries at a young age are known to be at high risk for developing further caries as they get older. Therefore, the appropriate prevention of ECC can result in the elimination of major dental problems in toddlers and less decay in later childhood.

Complications.

If left untreated, dental caries usually destroy most of the tooth and invade the dental pulp (Fig. 293–3), leading to an inflammation of the pulp (pulpitis) and significant pain. Pulpitis can progress to necrosis, with bacterial invasion of the alveolar bone causing a dental abscess. Infection of a primary tooth may disrupt normal development of the successor permanent tooth. In a small percentage of cases this

process may lead to sepsis and facial space infection (Fig. 293–4).

Treatment.

The age at which caries occurs is important in dental management. Children younger than 3 yr of age lack the developmental ability to cooperate with dental treatment and often require restraint, sedation, or general anesthesia to repair carious teeth. After age 4, children generally can cope with dental restorative care with the use of local anesthesia.

Dental treatment, using silver amalgam, plastic composite restorations, or stainless steel crowns, can restore most teeth affected with dental caries. If caries involve the dental pulp, a partial removal of the pulp (pulpotomy) or complete removal of the pulp (pulpectomy) may be required. If a tooth requires extraction, a space maintainer may be indicated to prevent migration of teeth that subsequently leads to malposition of permanent successor teeth.

Clinical management of the pain and infection associated with untreated dental caries varies with the extent of involvement and the medical status of the patient. Dental infection localized to the dentoalveolar unit can be managed by local measures (extraction, pulpectomy). Oral antibiotics are indicated for dental infections associated with cellulitis, facial swelling, or if it is difficult to anesthetize the tooth in the presence of inflammation. Penicillin is the antibiotic of choice, except in patients with a history of allergy to this agent; clindamycin and erythromycin are suitable alternatives. Oral analgesics, such as ibuprofen, are usually adequate for the pain control. If the infection involves a vital

Figure 293-2 Early childhood caries, also called nursing bottle caries or baby bottle tooth decay.

Figure 293-3 Basic dental anatomy: 1 = enamel; 2 = dentin; 3 = gingival margin; 4 = pulp; 5 = cementum; 6 = periodontal ligament; 7 = alveolar bone; 8 = neurovascular bundle.

Figure 293-4 *A*, Facial inflammation-infection from the abscess of a maxillary primary molar. *B*, Resolution of the inflammation in 1 wk with a course of antibiotics and extraction of the tooth.

area (submandibular space, which can lead to Ludwig angina; facial triangle, which can lead to cavernous sinus thrombosis; or periorbital space, which can rarely lead to orbital involvement), parenteral antibiotics are indicated.

Prevention

FLUORIDE.

The most effective preventive measure against dental caries is optimizing the fluoride content of communal water supplies to 1?ppm. Children who reside in areas with fluoride-deficient water supplies and are at caries risk will benefit from dietary fluoride supplements (Table 293–1). The fluoride level of public water supplies can usually be obtained by calling the local health department. If the patient uses a private water supply, it is necessary to get the water tested for fluoride levels before prescribing fluoride supplements. To avoid potential overdoses, no fluoride prescription should be written for more than a total of 120?mg of fluoride. Significant acute overdose of fluoride (greater than 5?mg/kg) needs immediate medical attention. The use of topical fluoride agents, applied professionally or by the patient, is beneficial to children at risk for caries.

TABLE 293-1 -- **Supplemental Fluoride Dosage Schedule**

Age	Fluoride in Home Water (ppm)		
	<0.3	***0.3–0.6***	***>0.6***
6 mo–3 yr	0.25*	0	0
3–6 yr	0.50	0.25	0
6–16 yr	1.00	0.50	0

Milligrams of fluoride per day.

ORAL HYGIENE.

Daily brushing, especially with fluoridated toothpaste, will help prevent dental caries. Most children under 8 yr of age do not have the coordination required for adequate tooth brushing. Accordingly, parents should assume responsibility for the child's oral hygiene, with the degree of parental involvement appropriate to the child's changing abilities. Only a pea-sized amount, or less, of fluoridated toothpaste should be used in young children who cannot adequately expectorate.

DIET.

Decreasing the frequency of sugar ingestion prevents dental caries. Therefore, using sweetened beverages in the nursing bottle and bedtime bottle should be discouraged, and children at risk for dental caries should reduce between-meal sugar-containing snacks.

DENTAL SEALANTS.

Plastic dental sealants have been shown to be effective in the prevention of caries on the pit and fissure of the primary and permanent molars. Sealants are most effective when placed soon after teeth erupt (usually within 1–2 yr) and when used in children with deep grooves and fissures in the molar teeth.

Chapter 294 - Periodontal Diseases

The periodontium includes the gingiva, alveolar bone, cementum, and periodontal ligament (see Fig. 293–3).

Gingivitis.

Poor oral hygiene results in the accumulation of a dental plaque at the tooth-gingival interface that activates an inflammatory response, expressed as localized or generalized reddening and swelling of the gingiva. Over half of American schoolchildren experience gingivitis. In severe cases, the gingiva spontaneously bleeds and there is oral malodor. *Treatment* is with proper oral hygiene (careful tooth brushing and flossing); complete resolution can be expected. Gingivitis in healthy prepubertal children is unlikely to progress to periodontitis (inflammation of the periodontal ligament resulting in loss of alveolar bone). Inability to resolve gingivitis by oral hygiene measures necessitates considering other problems in which gingivitis may be a presenting component (leukemia, diabetes mellitus, neutropenia, thrombocytopenia, scurvy, and hormonal changes associated with puberty and pregnancy).

Prepubertal Periodontitis.

Periodontitis in children before puberty, leading to premature loss of primary teeth, is often associated with systemic problems, including neutropenia, leukocyte adhesion or migration defects, hypophosphatasia, Papillon-Lefèvre syndrome, and histiocytosis X. In many cases, however, there is no apparent underlying medical problem. *Treatment* includes aggressive professional tooth cleaning, strategic extraction of affected teeth, and antibiotic therapy. Although there are few reports of long-term successful treatment to reverse bone loss surrounding primary teeth, diagnostic work-ups are necessary to rule out underlying systemic disease.

Localized Juvenile Periodontitis.

Localized juvenile periodontitis is characterized by rapid alveolar bone loss, especially around the permanent incisors and first molars. It is associated with a strain of *Actinobacillus*. In addition, the neutrophils of patients with localized juvenile periodontitis may have chemotactic and phagocytic defects. If left untreated, affected teeth lose their attachment and may exfoliate. *Treatment* varies with the degree of involvement. Patients diagnosed at the onset of the disease are usually managed by local debridement, antibiotic therapy, and meticulous oral hygiene. Patients who have extensive alveolar bone loss at the time of initial diagnosis require extensive

periodontal therapy that may include autologous osseous grafting. Prognosis depends on the degree of initial involvement and compliance with therapy.

Teething.

Teething can lead to intermittent localized discomfort in the area of erupting primary teeth, irritability, low-grade fevers, and excessive salivation; many children have no apparent difficulties. *Symptomatic treatment* includes chewing on ice rings and oral analgesics. Similar manifestations can also arise when the first permanent molars erupt at about age 6 yr.

Cyclosporine- or Phenytoin-Induced Gingival Overgrowth.

The use of cyclosporine to suppress organ rejection or phenytoin for anticonvulsant therapy, and in some cases calcium channel blockers, is associated with generalized enlargement of the gingiva. Phenytoin and its metabolites have a direct stimulatory action on gingival fibroblasts, resulting in accelerated synthesis of collagen. Clinical studies indicate that phenytoin induces less gingival hyperplasia in patients who maintain meticulous oral hygiene.

Gingival hyperplasia occurs in 10–30% of patients treated with phenytoin. Severe manifestations may include (1) gross enlargement of the gingiva, sometimes covering the teeth; (2) edema and erythema of the gingiva; (3) secondary infection, resulting in abscess formation; (4) migration of teeth; and (5) inhibition of exfoliation of primary teeth and subsequent impaction of permanent teeth. *Treatment* should be directed toward prevention and, if possible, discontinuation of cyclosporine or phenytoin. Patients undergoing long-term treatment with these drugs should receive frequent dental examinations and oral hygiene care. Severe forms of gingival overgrowth are treated by gingivectomy, but the lesion recurs if drug use is continued.

Acute Pericoronitis.

Acute inflammation of the flap of gingiva that partially covers the crown of an incompletely erupted tooth is common in mandibular permanent molars. Accumulation of debris and bacteria between the gingival flap and tooth precipitates the inflammatory response. A variant of this condition is a gingival abscess due to entrapment of bacteria because of orthodontic bands or crowns. Trismus and severe pain may be associated with the inflammation. Untreated cases may result in facial space infections and facial cellulitis.

Treatment includes local debridement and irrigation, warm saline rinses, and antibiotic therapy. When the acute phase has subsided, extraction of the tooth or resection of the gingival flap prevents recurrence. Early recognition of the partial impaction of mandibular third molars and their subsequent extraction will prevent these areas from having pericoronitis.

Acute Necrotizing Ulcerative Gingivitis.

Acute necrotizing ulcerative gingivitis (ANUG), also called Vincent stomatitis and trench mouth, is a distinct periodontal disease associated with oral spirochetes and fusobacteria. It is not clear, however, whether bacteria initiate the disease or are secondary. ANUG develops primarily in young adults and adolescents. It rarely develops in healthy children in developed countries. It occurs frequently among children in southern India and certain African countries where affected children usually have protein malnutrition. In such children, the lesion may extend into adjacent tissues, causing necrosis of facial structures (cancrum oris, or noma).

Clinical manifestations of ANUG include (1) necrosis and ulceration of gingiva between the teeth, (2) an adherent grayish pseudomembrane over the affected gingiva, (3) oral malodor,

(4) cervical lymphadenopathy, (5) malaise, and (6) fever. The condition may be mistaken for acute herpetic gingivostomatitis. Dark-field microscopy of debris obtained from ANUG lesions will demonstrate dense spirochete populations.

Treatment of ANUG is divided into an acute management with antibiotics (penicillin or erythromycin), local debridement, oxygenating agents (direct application of 10% carbamide peroxide in anhydrous glycerol qid), and analgesics. Dramatic resolution usually occurs within 48?hr. A second phase of treatment may be necessary if the acute phase of the disease has caused irreversible morphologic damage to the periodontium. The disease is not contagious.

Chapter 295 - Dental Trauma

Traumatic oral injuries may be categorized into three groups: (1) injuries to teeth, (2) injuries to soft tissue (contusions, abrasions, lacerations, punctures, avulsions, and burns), and (3) injuries to jaw (mandibular or maxillary fractures or both).

Injuries to Teeth.

Approximately 10% of children between 18 mo and 18 yr of age will sustain significant tooth trauma. There appear to be three age periods of greatest predilection: (1) toddlers (1–3 yr), usually due to falls or child abuse; (2) school-aged (7–10 yr), usually from bicycle and playground accidents; and (3) adolescents (16–18 yr), often the result of fights, athletic injuries, and automobile accidents. Injuries to teeth are more frequent among children with protruding front teeth. Children with craniofacial abnormalities or neuromuscular deficits are also at increased risk for dental injury. Injuries to teeth may involve the hard dental tissues, the dental pulp (nerve), and injuries to the periodontal structure (surrounding bone and attachment apparatus) (Fig. 295–1 ; Table 295–1).

Fractures of teeth may be uncomplicated (confined to the hard dental tissues) or complicated (involving the pulp). Exposure of the pulp will result in its bacterial contamination, which can lead to infection and pulp necrosis. Such pulp exposure complicates therapy and may lower the likelihood of a favorable outcome.

The teeth most often affected are the maxillary incisors. Uncomplicated crown fractures are treated by covering exposed dentin and by placing an aesthetic restoration. Complicated crown fractures usually require endodontic (root canal) therapy. Crown-root fractures and root fractures usually require extensive dental therapy. Such injuries in the primary dentition may interfere with normal development of the permanent dentition, and, therefore, significant injuries of the primary incisor teeth are usually managed by extraction.

Injuries to Crowns of Teeth

Type of Trauma	Description	Treatment and Referral
Enamel infraction (crazing)	Incomplete fracture of enamel without loss of tooth structure.	Initially may not require therapy but should be assessed periodically by dentist.
Enamel fractures	Fracture of only the tooth enamel.	Tooth may be smoothed or treated to replace fragment.
Enamel and dentin fracture	Fracture of enamel and dentinal layer of the tooth. Tooth may be sensitive to cold or air. Pulp may become necrotic, leading to periapical abscess.	Refer as soon as possible. Area should be treated to preserve the integrity of the underlying pulp.
Enamel, dentin fracture involving the pulp	Bacterial contamination may lead to pulpal necrosis and periapical abscess. The tooth may have the appearance of bleeding or may display a small red spot.	Refer immediately. The dental therapy of choice depends on the extent of injury, the condition of the pulp, the development of the tooth, time elapsed from injury, and any other injuries to the supporting structures. Therapy is directed toward minimizing contamination in an effort to improve the prognosis.

From Jossell SD, Abrams RG: Managing common dental problems and emergencies. Pediatr Clin North Am 1991;38:1325.

Figure 295-1 Tooth fractures may involve enamel, dentin, or pulp and may occur in the crown or root of a tooth. (From Pinkham JR: *Pediatric Dentistry: Infancy Through Adolescence.* Philadelphia, WB Saunders, 1988, p 172.)

Traumatic oral injuries should be referred to a dentist as soon as possible. Even when the teeth appear intact, a dentist should evaluate the patient promptly. Baseline data (radiographs, mobility patterns, responses to specific stimuli) enable the dentist to assess the likelihood of future complications.

Injuries to Periodontal Structures.

Trauma to teeth with associated injury to periodontal structures that hold the teeth usually presents as mobile or displaced teeth. Such injuries are more frequent in the primary than in the permanent dentition. Categories of trauma to the periodontium include (1) concussion, (2) subluxation, (3) intrusive luxation, (4) extrusive luxation, and (5) avulsion.

CONCUSSION.

Injuries that produce minor damage to the periodontal ligament are termed *concussions*. Teeth sustaining such injuries are not mobile or displaced but react markedly to percussion (gentle hitting of the tooth with an instrument). This type of injury usually requires no therapy and resolves without complication. Primary incisors that sustain concussion may change color, indicating pulpal degeneration, and should be evaluated by a dentist.

SUBLUXATION.

Subluxated teeth exhibit mild to moderate horizontal mobility, vertical mobility, or both. Hemorrhage is usually evident around the neck of the tooth at the gingival

margin. There is no displacement of the tooth. Many subluxated teeth need to be immobilized by splints to ensure adequate repair of the periodontal ligament. Some of these teeth will develop pulp necrosis.

INTRUSIVE LUXATION.

Intruded teeth are pushed up into their socket, sometimes to the point where they are not clinically visible. Intruded primary incisors may give the false appearance of being avulsed (knocked out) (Fig. 295–2). To rule out avulsion, a dental radiograph is indicated (Fig. 295–3).

EXTRUSIVE LUXATION.

This type of injury is characterized by displacement of the tooth from its socket. The tooth is usually displaced to the lingual (tongue) side, with fracture of the wall of the alveolar socket. These teeth need immediate treatment; the longer the delay, the more likely the tooth will be fixed in its displaced position. Therapy is directed at reduction (repositioning the tooth) and fixation (splinting). In addition, the pulp of such teeth often becomes necrotic and requires endodontic therapy. Extrusive luxation in the primary dentition is usually managed by extraction because complications of reduction and fixation may result in problems with development of permanent teeth.

AVULSION.

If avulsed permanent teeth are replanted within 20?min after injury, good success may be achieved; if the delay exceeds 2?hr, however, failure (root resorption, ankylosis) is frequent. The likelihood that normal reattachment will follow replantation of the tooth is related to the viability of the periodontal ligament. Parents confronted with this emergency situation can be instructed to do the following:

1. Find the tooth.
2. Rinse the tooth. (Do not scrub the tooth. Do not touch the root. After plugging the sink drain, hold the tooth by the crown and rinse it under running tap water.)
3. Insert the tooth into the socket. (Gently place it back into its normal position. Do not be concerned if the tooth extrudes slightly. If the parent or child is too apprehensive for replantation of the tooth, the tooth should be placed in cold cow's milk or other cold isotonic solutions).
4. *Go directly to the dentist*. (In transit, the child should hold the tooth in place with a finger. The parent should buckle a seatbelt around the child and drive safely.)

Figure 295-2 Intruded primary incisor that appears avulsed (knocked out).

Figure 295-3 Occlusal radiograph documents intrusion of "missing tooth" presented in Figure 295–2 .

After the tooth is replanted, it must be immobilized to facilitate reattachment; endodontic therapy is always required. The initial signs of complications associated with replantation may appear as early as 1 wk post trauma or as late as several years later. Close dental follow-up is indicated for at least 1 yr.

PREVENTION

To minimize the likelihood of dental injuries:

1. Every child or adolescent who engages in contact sports should wear a mouth guard, which may be constructed by a dentist or purchased at any athletic goods store.
2. Helmets with face guards should be worn by children or adolescents with neuromuscular problems or seizure disorders to protect the head and face during falls.
3. Helmets should also be used during biking, roller blading, and skateboarding.
4. All children or adolescents with protruding incisors should be evaluated by a pediatric dentist or orthodontist.

Additional Considerations.

Children who experience dental trauma may also have sustained head or neck trauma, and therefore neurologic assessment is warranted. Tetanus prophylaxis should be considered with any injury that disrupts the integrity of the oral tissues. The possibility of child abuse should always be considered.

Chapter 296 - Common Lesions of the Oral Soft Tissues

Oropharyngeal Candidiasis (see Chapter 215.1).

Oropharyngeal infection with *Candida albicans* (thrush, moniliasis) is common in neonates from contact with the organism in the birth canal. The lesions of oropharyngeal candidiasis (OPC) appear as white plaques covering all or part of the oropharyngeal mucosa. These plaques are removable from the underlying surface, which is characteristically inflamed with pinpoint hemorrhages. The diagnosis is confirmed by direct microscopic examination on potassium hydroxide smears and culture of scrapings from lesions. OPC is usually self-limited in the healthy newborn infant, but treatment with nystatin will hasten recovery and reduce the risk of spreading to other infants. Persistent infections should be treated with fluconazole therapy.

Oropharyngeal candidiasis is also a major problem during myelosuppressive therapy. Systemic candidiasis (SC), a major cause of morbidity and mortality during myelosuppressive therapy, develops almost exclusively in patients who have had prior oropharyngeal, esophageal, or intestinal candidiasis. This observation implies that prevention of OPC should reduce the incidence of SC. The use of a multiagent regimen, 0.2% chlorhexidine solution and fluconazole, for OPC prophylaxis in children receiving bone marrow transplants may be effective in preventing OPC, SC, or candidal esophagitis.

Aphthous Ulcers.

The aphthous ulcer (canker sore) is a distinct oral lesion, prone to recurrence. The differential diagnosis is noted in Table 296–1 . Aphthous ulcers are reported to develop

in 20% of the population. Their etiology is unclear, but infectious causes, such as *Helicobacter pylori*, herpes simplex virus, and even measles are have been implicated. Clinically, they are characterized by well-circumscribed, ulcerative lesions with a white necrotic base surrounded by a red halo. The lesions last 10 to 14 days and heal without scarring. Expensive prescription medications appear to offer little advantage over readily available over-the-counter palliative therapies.

Herpetic Gingivostomatitis (see Chapter 231).

After an initial incubation period of approximately 1 wk, the initial infection with herpes simplex virus manifests as fever and malaise. The oral cavity may show various expressions, including the gingiva becoming erythematous and clusters of small vesicles erupting throughout the mouth. The symptoms usually regress within 2 wk without scarring. Fluids should be encouraged because the child may become dehydrated. Analgesics and anesthetic rinses may make the child more comfortable. Caution should be exercised to prevent autoinoculation or transmission of infection to the eyes.

Recurrent Herpes Labialis.

Approximately 90% of the population develops antibodies to herpes simplex virus. In periods of quiescence, the virus is thought to remain latent in sensory neurons. Unlike primary herpetic gingivostomatitis, which manifests as multiple painful vesicles on the lips, tongue, palate, gingiva, and mucosa, recurrent herpes is generally limited to the lips. Other than the annoyance of causing pain and an unattractive appearance, there are generally no systemic symptoms. Reactivation of the virus is thought to be the result of exposure to ultraviolet light, tissue trauma, stress, or fevers. There is little advantage of antiviral therapy over palliative therapies in an otherwise healthy patient affected by recurrent herpes.

Bohn Nodules.

Bohn nodules are small developmental anomalies located along the buccal and lingual aspects of the mandibular and maxillary ridges and in the hard palate of the neonate. These lesions arise from remnants of mucous gland tissue. Treatment is not necessary, as the nodules disappear within a few weeks.

Dental Lamina Cysts.

Dental lamina cysts are small cystic lesions located along the crest of the mandibular and maxillary ridges of the neonate. These lesions arise from epithelial remnants of the dental lamina. Treatment is not necessary; they will disappear within a few weeks.

TABLE 296-1 -- Differential Diagnosis of Oral Ulceration

Condition	Comment
Common	
Aphthous (canker sore)	Painful, circumscribed lesions

Traumatic	Accidents, chronic cheek biter or after dental local anesthesia
Hand, foot, mouth disease	Painful, lesions on tongue, anterior oral cavity, hands and feet
Herpangina	Painful, lesions confined to soft palate and oropharynx
Herpetic gingivostomatitis	Vesicles on mucocutaneous borders; painful, febrile
Recurrent herpes labialis	Vesicles on lips; painful
Chemical burns	Alkali, acid, aspirin; painful
Heat burns	Hot food, electrical
Uncommon	
Neutrophil defects	Agranulocytosis, leukemia, cyclic neutropenia; painful
Systemic lupus erythematosus	Recurrent, may be painless
Behçet's syndrome	Resembles aphthous lesions; associated with genital ulcers, uveitis, etc.
Necrotizing ulcerative gingivostomatitis	Vincent stomatitis; painful
Syphilis	Chancre or gumma; painless
Oral Crohn disease	Aphthous-like; painful
Histoplasmosis	Lingual

Fordyce Granules.

Almost 80% of adults have multiple, yellow-white granules in clusters or plaquelike areas on the oral mucosa, most commonly on the buccal mucosa or lips. They are aberrant sebaceous glands. The glands are present at birth, but they may hypertrophy and first appear as discrete yellowish papules during the preadolescent period in approximately 50% of children. No treatment is necessary.

Parulis.

The parulis (gum boil) is a soft, reddish papule located adjacent to the root of a chronically abscessed tooth. It occurs at the endpoint of a draining dental sinus tract. Treatment consists of diagnosing which tooth is abscessed and extracting it or root canal treatment of the offending tooth.

Cheilitis.

Dryness of the lips, followed by scaling and cracking and accompanied by a characteristic burning sensation, is common in children. It is usually caused by sensitivity to contact substances (from toys and foods) plus photosensitivity to the sun's rays. It is aggravated by the alternation of wetting with the tongue and drying by the wind, especially in cold weather. Cheilitis often occurs in association with fever. Frequent application of petroleum jelly facilitates healing and is also preventative.

Ankyloglossia.

Ankyloglossia or “tongue-tie” is characterized by an abnormally short lingual frenum that hinders the tongue movement. The frenum may lengthen as the child gets older. If the extent of the ankyloglossia is severe, speech may be affected and surgical correction indicated.

Geographic Tongue.

Geographic tongue (migratory glossitis) is a benign and asymptomatic lesion and is characterized by one or more smooth, bright-red patches, often showing a yellow, gray, or white membranous margin on the dorsum of an otherwise normally roughened tongue. The condition has no known cause and no treatment is indicated (see Chapter 654).

Fissured Tongue.

The fissured tongue (scrotal tongue) is a malformation manifested clinically by numerous small furrows or grooves on the dorsal surface (see Chapter 654). If the tongue is painful, the bacteria in the fissures can be reduced by brushing the tongue or use of water irrigation.

Chapter 297 - Diseases of the Salivary Glands and Jaws

With the exception of mumps (see Chapter 227), disease of the salivary glands is rare in children. Bilateral enlargement of the submaxillary glands may occur in AIDS, cystic fibrosis, and malnutrition and, transiently, during acute asthmatic attacks. Chronic vomiting may be accompanied by enlargement of the parotid glands. Benign salivary gland hypertrophy has been associated with endocrinopathies: thyroid disease, diabetes, and disorders of the pituitary-adrenal axis.

Recurrent Parotitis.

Recurrent idiopathic swelling of the parotid gland may occur in otherwise healthy children. The swelling is usually unilateral, but both glands may be involved simultaneously or alternately. There is little pain; the swelling is limited to the gland and usually lasts 2–3 wk. The incidence appears to be higher in the spring.

Suppurative Parotitis.

This is usually due to *Staphylococcus aureus* and may be primary or a complication of parotitis from another cause. It is usually unilateral and may be accompanied by fever. The gland becomes swollen, tender, and painful. Suppurative parotitis responds to appropriate antibacterial therapy based on

culture obtained from the Stensen duct or by surgical drainage, which is infrequently required.

Ranula.

Ranula is a cyst associated with a major salivary gland in the sublingual area. A ranula is a large, soft, mucus-containing swelling in the floor of the mouth. It occurs at any age, including infancy. The cyst should be excised, and the severed duct should be exteriorized.

Mucocele.

A mucocele is a salivary gland lesion caused by a blockage of a salivary gland duct. They are most common on the lower lip and have the appearance of a fluid-filled vesicle or a fluctuant nodule with the overlying mucosa normal in color. Treatment is by surgical excision with removal of the involved accessory salivary gland.

Congenital Lip Pits.

Lip pits are caused by fistulous tracts that lead to imbedded mucus glands in the lower lip. They leak saliva, especially with salivary stimulation. Lip pits may be isolated anomalies, or they may be found in patients with cleft lip or palate. Treatment is by surgical excision of the glandular tissue.

Eruption Cyst.

An eruption cyst is a smooth painless swelling over the erupting tooth. If bleeding occurs in the cyst space, it may appear blue or blue-black. In most cases, no treatment is indicated and the cyst will resolve with the full eruption of the tooth.

Xerostomia.

Xerostomia (or dry mouth) may be associated with fever, dehydration, anticholinergic drugs, chronic graft versus host disease, Mikulicz disease (leukemia infiltrates), Sjögren syndrome, or tumoricidal doses of radiation when the salivary glands are within the field. Long-term xerostomia is a high risk factor for dental caries.

Salivary Gland Tumors.

See Chapter 492.1 .

Histiocytosis X (see Chapter 499).

The etiology and pathogenesis of histiocytosis remains obscure. In the severe form there are oral lesions with pain, swelling, gingival necrosis, and destruction of alveolar bone resulting in premature exfoliation of teeth. Treatment will vary according to the extent of the disease, with surgical curettage or radiation therapy being used to treat the focal disease. Multiagent chemotherapy is successful in treating the disseminated disease.

Tumors of the Jaws.

Ossifying fibroma is a common benign tumor of the jaw. It is often asymptomatic, being discovered on routine radiographic examinations. Treatment is by enucleation or curettage. Central giant cell granuloma is another common lesion thought to be reactive rather than neoplastic. Although usually asymptomatic, it may be expansile with or without divergence of teeth. Treatment is by complete curettage or surgical excision. Dentigerous cysts are common lesions associated with the crown of an impacted or unerupted tooth. Although usually asymptomatic they may become large and destructive. Treatment is by surgical removal.

The malignant primary tumors of the jaws in children include Burkitt lymphoma, osteogenic sarcoma, lymphosarcoma, ameloblastoma, and, more rarely, fibrosarcoma.

Chapter 298 - Diagnostic Radiology in Dental Assessment

The *panoramic radiograph* provides a single tomographic image of the upper and lower jaw, including all the teeth and supporting structures. The x-ray tube rotates about the patient's head with reciprocal movement of the film or image receptor during the exposure. The panoramic image shows the mandibular bodies,

Figure 298-1 A panoramic radiograph of an 8-yr-old patient with a cleft palate showing abnormal numbers and position of teeth in the area of the cleft (*arrows*). Also shown are erupted primary teeth (ep), erupted permanent teeth (EP), and unerupted permanent teeth (UP).

rami, and condyles; maxillary sinuses; and a majority of the facial buttresses. Such images are used to show abnormalities of tooth number, development and eruption pattern, cystic and neoplastic lesions, extensive bone infections, and fractures (Fig. 298–1).

Cephalometric radiographs are posteroanterior and lateral skull films that are taken using a head positioner (cephalostat) and employ techniques that clearly demonstrate the facial skeleton and soft facial tissues. Similar protocols for positioning children are used throughout the world. From these images, cranial and facial points and planes can be determined and compared with standards derived from thousands of images. A child's facial growth can be assessed serially when cephalometric radiographs are taken sequentially. Relationships among the maxilla, mandible, cranial base, and facial skeleton can be determined in a quantitative manner. Additionally, the alignment of the teeth and the relation of the teeth to the supporting bone can be serially measured.

Intraoral dental radiographs are highly detailed, direct exposure films that demonstrate sections of the child's teeth and supporting bone structures. The film or image receptor is placed lingual to the teeth, and the x-ray beam is directed through the teeth and supporting structures. The resulting images are used to detect dental caries, loss of alveolar bone (periodontal disease), abscesses at the roots of the teeth, and trauma to the teeth and alveolar bone and to demonstrate the developmental status of permanent teeth within the bone.

Chapter 299 - Embryology, Anatomy, and Function of the Esophagus

The esophagus is a hollow muscular tube, separated from the pharynx above and the stomach below by two tonically closed sphincters. Its primary function is to convey ingested material from the mouth to the stomach. Largely lacking digestive glands and enzymes, and exposed only briefly to nutrients, it has no active role in digestion.

Embryology.

The esophagus develops from the postpharyngeal foregut and can be distinguished from the stomach in the 4-week (5-mm) embryo. At the same time, the trachea begins to bud just anterior to the developing esophagus; the resulting laryngotracheal groove extends and becomes the lung. Disturbances in this stage may result in congenital anomalies such as tracheoesophageal fistula. The length of the esophagus is 2.5?mm in a 13.5-mm embryo, is 8–10?cm at birth, and doubles during the first 2–3 yr of life, reaching approximately 25?cm in an adult. The abdominal portion of the esophagus is as large as the stomach in an 8-wk old fetus but gradually shortens to a few millimeters at birth, attaining a final length of about 3?cm by a few years of age. This intra-abdominal location of both the distal esophagus and the lower esophageal sphincter (LES) is an important antireflux mechanism, because increase in intra-abdominal pressure is also transmitted to the sphincter, augmenting its defense. Swallowing can be seen in utero as early as 16–20 wk of gestation, helping to circulate the amniotic fluid; polyhydramnios is thus a hallmark of lack of normal swallowing or of esophageal or gastrointestinal obstruction. Sucking and swallowing are not fully coordinated before 34 wk of gestation, a contributing factor for feeding difficulties in premature infants.

Anatomy.

The luminal aspect of the esophagus is covered by thick, protective, nonkeratinized stratified squamous epithelium, which abruptly changes to simple columnar epithelium at the stomach's upper margin at the gastroesophageal junction (GEJ). This squamous epithelium is relatively resistant to damage by gastric secretions (in contrast to the ciliated columnar epithelium of the respiratory tract), but chronic irritation by gastric contents may result in morphometric changes (see morphometric esophagitis, later) and subsequent metaplasia of the cells lining the lower esophagus from squamous to columnar. Deeper layers of the esophageal wall are composed successively of lamina propria, muscularis mucosae, submucosa, and the two layers of muscularis propria (circular surrounded by longitudinal). The two delimiting sphincters of the esophagus, the upper esophageal sphincter (UES) at the cricopharyngeus muscle and the LES at the GEJ, narrow the caliber of the esophageal lumen at its proximal and distal boundaries. The muscularis propria of the upper third of the esophagus is predominantly striated, and that of the lower two thirds is smooth muscle. Clinical conditions involving striated muscle (cricopharyngeal dysfunction, cerebral palsy) affect the upper esophagus, whereas those involving smooth muscle (achalasia, reflux esophagitis) affect the lower esophagus. The muscular LES and the mucosal “Z-line” of the GEJ may be discrepant up to several centimeters.

Function.

The esophagus can be divided into three areas: the UES, the esophageal body, and the LES. At rest, the tonic LES pressure is normally about 20?mm?Hg; values below 10?mm?Hg are usually considered abnormal, although it seems that competence against retrograde flow of gastric material is maintained if the LES pressure is above 5?mm?Hg. The LES pressure rises during intragastric pressure amplifications, whether caused by gastric contractions, abdominal wall muscle contractions (“straining”), or external pressure applied to the abdominal wall. It also rises in response to cholinergic stimuli, gastrin, gastric alkalization, and certain drugs (bethanechol, metoclopramide, cisapride). The UES pressure is more variable and often higher than that of the LES; it decreases almost to zero during deep sleep but increases markedly during stress and straining.

Swallowing is initiated by elevation of the tongue, propelling the bolus into the pharynx. The larynx elevates and moves anteriorly, pulling open the relaxing UES, while the epiglottis drops back to cover the larynx and direct the bolus over the larynx and into the UES and the soft palate occludes the nasopharynx. The primary peristalsis thus initiated is a contraction originating in the oropharynx that clears the esophagus aborally (Fig. 299–1). The LES, tonically contracted as a barrier against gastroesophageal reflux, relaxes as swallowing is initiated, at nearly the same time as the UES relaxation. However, the LES relaxation persists considerably longer, until the peristaltic wave traverses it and closes it. The normal esophageal peristaltic speed is about 3?cm/s; the wave takes at least 4?s to traverse the 12-cm esophagus of a young infant and considerably longer in a larger child. Facial stimulation by a puff of air can induce swallowing and esophageal peristalsis in healthy young infants,

a reflex termed the *Santmyer swallow*.

In addition to relaxing to move swallowed material past the GEJ into the stomach, the LES normally relaxes to vent swallowed air or to allow retrograde expulsion of material from the stomach. Perhaps as an extension of these functions, the normal LES also permits physiologic reflux episodes that are brief and occur approximately five times in the first postprandial hour but uncommonly otherwise. Transient LES relaxation, not associated with swallowing, comprises the major mechanism underlying pathologic reflux (see Fig. 299–1).

The close linkage of the anatomy of the upper digestive and respiratory tracts has mandated intricate functional protections of the respiratory tract during retrograde movement of gastric contents as well as during swallowing. The protective functions include the LES tone, the bolstering of the LES by the surrounding diaphragmatic crura, and the “backup protection” of the UES tone. In addition, secondary (“esophageal”) peristalsis, akin to primary peristalsis but without an oral component, clears refluxed gastric contents from the esophagus. Another protective reflex is the “pharyngeal swallow” (initiated above the esophagus, but without lingual participation). Multiple levels of protection against aspiration include the rhythmic coordination of swallowing and breathing as well as a series of protective reflexes with esophagopharyngeal afferents and efferents that close the UES or larynx. These reflexes include the esophago-UES contractile reflex, the pharyngo-UES contractile reflex, the esophagoglottal closure reflex, and two pharyngoglottal adduction reflexes. The latter two reflexes have chemoreceptors on the laryngeal surface of the epiglottis and mechanoreceptors on the aryepiglottic folds as their sites of stimulus. It is likely that interactions between the esophagus and the respiratory tract, which cause extraesophageal manifestations of gastroesophageal reflux

Figure 299-1 A continuous tracing of esophageal motility showing 2 swallows, as indicated by the pharyngeal contraction associated with relaxation of the UES and followed by peristalsis in the body of the esophagus. The LES also displays a transient relaxation *(arrow)* unassociated with a swallow. There is an episode of gastroesophageal reflux (*) recorded by a pH probe at the time of the transient LES relaxation. (Courtesy of John Dent, FRACP, PhD, and Geoffrey Davidson, MD.)

disease, will be explained by subtle abnormalities in these protective reflexes.

299.1 Common Clinical Manifestations and Diagnostic Aids

Common Clinical Manifestations.

Manifestations of esophageal disease may be categorized as pain, obstruction or difficulty swallowing, abnormal retrograde movement of gastric contents (reflux, regurgitation, or vomiting), or bleeding; esophageal disease may also engender respiratory symptoms. Pain in the chest unrelated to swallowing (“heartburn”) can be a sign of esophagitis, but similar pain may also represent cardiac, pulmonary, or musculoskeletal disease. Pain during swallowing (odynophagia) localizes the disease more discretely to the pharynx and esophagus and often represents inflammatory mucosal disease. Complete esophageal obstruction may be produced acutely by esophageal foreign bodies, including food impactions; may be congenital, as in esophageal atresia; or may evolve over time as a peptic stricture occludes the esophagus. Difficulty swallowing (dysphagia) may be produced by incompletely occlusive esophageal obstruction (by extrinsic compression, intrinsic narrowing, or foreign bodies) but also may result from dysmotility of the esophagus (whether primary/idiopathic or secondary to systemic disease). Inflammatory lesions of the esophagus without obstruction or dysmotility are a third cause of dysphagia; eosinophilic esophagitis, most often afflicting older male children, is a relatively common cause. The most common esophageal disorder in children is gastroesophageal reflux disease (GERD), which is retrograde return of gastric contents. Esophagitis may be caused by GERD, by eosinophilic disease, by infection, or by caustic substances. Esophageal bleeding may result from severe esophagitis that produces erosions or ulcerations and may manifest as anemia or Hemoccult-positive stools. More acute or severe bleeding may be due to ruptured esophageal varices. The resulting hematemesis must be differentiated from more distal bleeding (gastric ulcer) and from more proximal bleeding (a nosebleed or hemoptysis). Respiratory symptoms of esophageal disease may result from luminal contents incorrectly being directed into the respiratory tract or to reflexive respiratory responses to esophageal stimuli.

Diagnostic Aids.

The esophagus may be evaluated by radiography, endoscopy, histology, scintigraphy, manometry, pH-metry (linked as indicated with other polysomnography), and intraluminal impedance. Contrast (usually barium) radiographic study of the esophagus usually incorporates fluoroscopic imaging over time so that motility, as well as anatomy, can be assessed. Although most often requested to evaluate for GERD, it is neither sensitive nor specific for this purpose; however, it can detect complications of GERD (stricture or hiatal hernia) or conditions mimicking GERD (pyloric stenosis or malrotation with intermittent volvulus). Barium fluoroscopy is optimal to evaluate for structural anomalies, such as duplications, strictures, or external esophageal compression by an aberrant blood vessel, or for causes of dysmotility, such as achalasia. Modifications of the routine barium fluoroscopic study are used in special situations. When an “H-type” tracheoesophageal fistula is suspected, the test is most sensitive if the radiologist distends the esophagus with barium via a nasogastric tube with the patient prone. A “modified barium swallow” performed with varying consistencies of barium (oropharyngeal videoesophagogram or “cookie swallow”) optimally evaluates children with dysphagia by demonstrating incoordination in the pharyngeal and esophageal phases of swallowing. In some centers videofluoroscopy is combined with fiberoptic (naso)pharyngeal endoscopy to provide exquisite detail when UES dysfunction is suspected. Endoscopy allows direct visualization of esophageal mucosa and helps therapeutically in the removal of foreign bodies and treatment of esophageal varices. Endoscopy also allows biopsy samples to be taken, thus improving the diagnosis of “endoscopy-negative” GERD, differentiating GERD from eosinophilic esophagitis, and identifying viral or fungal causes of esophagitis. Radionuclide scintigraphy scans are helpful in evaluating the efficiency of peristalsis and demonstrating reflux episodes. They can be specific, although not very sensitive, for aspiration and can quantify gastric emptying, thus hinting at a cause for GERD. Esophageal manometry evaluates for dysmotility from the pharynx to the stomach; by synchronized quantitative pressure measurements along the esophagus it detects

dysfunctions sometimes missed radiographically. Manometry is often challenging in young infants, and sphincters are optimally evaluated with a special Dent sleeve. Extended pH monitoring of the distal esophagus is a quantitative and sensitive test for acidic GER episodes. It is linked with polysomnography (a pneumogram) when GER is suspected to cause apnea or similar symptoms. Intraluminal electric impedance is a method for pH-independent detection of bolus movements in the esophagus and can distinguish between acid and nonacid liquid and gaseous reflux.

Chapter 300 - Congenital Anomalies: Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia (EA) is the most frequent congenital anomaly of the esophagus, affecting about 1 in 4,000 neonates. Of these, more than 90% have an associated tracheoesophageal fistula (TEF). In the most common form of EA, the upper esophagus ends in a blind pouch and the TEF is connected to the distal esophagus. The types of EA and TEF and their relative frequencies are shown in Figure 300–1 . This defect now has survival rates of greater than 90%, owing largely to improved neonatal intensive care, earlier recognition, and appropriate intervention. Infants weighing less than 1,500?g at birth have the highest risk for mortality. Fifty per cent of infants have associated anomalies, most often associated with the VATER/VACTERL (*V*ertebral, *A*norectal, *T*rachea, *E*sophagus, *C*ardiac, *R*enal, *R*adial, and *L*imb) syndrome.

Presentation.

The neonate with EA typically has frothing and bubbling at the mouth and nose, episodes of coughing, cyanosis, and respiratory distress. Feeding exacerbates these symptoms, causes regurgitation, and may precipitate aspiration. Aspiration of gastric contents via a distal fistula causes more damaging pneumonitis than aspiration of pharyngeal secretions from the blind upper pouch. The infant with an isolated TEF in the absence of EA ("H-type" fistula) may come to medical attention later in life with chronic respiratory problems, including refractory bronchospasm and recurrent pneumonias.

Diagnosis.

In the setting of early-onset respiratory distress, the inability to pass a nasogastric or orogastric tube in the newborn is suggestive of esophageal atresia. Prenatally, maternal polyhydramnios may alert the physician to EA. Plain radiography in the evaluation of respiratory distress may reveal a coiled feeding tube in the esophageal pouch and/or an air- distended stomach indicating the presence of a coexisting TEF (Fig. 300–2). Conversely, pure EA may present as an airless, scaphoid abdomen. In isolated TEF, an esophagogram with contrast medium injected under pressure may demonstrate the defect. Alternatively, the orifice may be detected at bronchoscopy or when methylene blue dye injected into the endotracheal tube during endoscopy is

observed in the esophagus during forced inspiration.

Management.

Initially, maintaining a patent airway and preventing aspiration of secretions is paramount. Prone positioning minimizes movement of gastric secretions into a distal fistula, and esophageal suctioning minimizes aspiration from a blind pouch. Endotracheal intubation is avoided because it may

Figure 300-1 Diagrams of the five most commonly encountered forms of esophageal atresia and tracheoesophageal fistula, shown in order of frequency.

worsen distention of abdominal viscera. Surgical ligation of the TEF and primary end-to-end anastomosis of the esophagus are performed when feasible. In the premature or otherwise complicated infant, a primary closure may be delayed by temporizing with fistula ligation and gastrostomy tube placement. If the gap between the atretic ends of the esophagus is greater than 3–4?cm, primary repair cannot be done; options include using gastric, jejunal, or colonic segments interposed as a neo-esophagus. Careful search must be undertaken for the common associated cardiac and other anomalies.

Figure 300-2 Tracheoesophageal fistula. Lateral radiograph demonstrating a nasogastric tube coiled *(arrows)* in the proximal segment of an atretic esophagus. The distal fistula is suggested by gaseous dilatation of the stomach (S) and small intestine. The *arrowhead* depicts vertebral fusion, whereas a heart murmur and cardiomegaly suggest the presence of a ventricular septal defect. This patient demonstrated elements of the VATER anomalad. (From Balfe D, Ling D, Siegel M: The esophagus. In Putman CE, Ravin CE [editors]: *Textbook of Diagnostic Imaging*. Philadelphia, WB Saunders, 1988.)

Outcome.

The majority of infants grow up to lead normal lives, but complications are frequently challenging, particularly during infancy. Complications of surgery include anastomotic leak, re-fistulization, and anastomotic stricture. Gastroesophageal reflux disease (GERD), resulting from intrinsic abnormalities of esophageal function, often combined with delayed gastric emptying, contributes to management challenges in many cases. GERD contributes significantly to the respiratory disease (reactive airway disease) that often complicates EA and TEF and also worsens the frequent anastomotic strictures after repair of EA.

300.1 Congenital Anomalies: Laryngotracheoesophageal Clefts

These uncommon anomalies result when the septum between the esophagus and trachea fails to develop fully, leading to a common channel defect between the pharyngoesophagus and laryngotrachea, and thus making the laryngeal closure incompetent during swallowing or reflux. Early in life, the infant presents with stridor, choking, cyanosis, aspiration of feedings, and recurrent chest infections. The diagnosis is difficult and usually requires direct visualization of the larynx and esophagus endoscopically. When contrast radiography is used, material is often seen in the esophagus and trachea. Treatment is by surgical repair, which can be complex if the defects are long.

Chapter 301 - Obstructing and Motility Disorders of the Esophagus

Obstructing lesions classically produce dysphagia to solids earlier and more noticeably than to liquids and may manifest when the infant liquid diet begins to incorporate solids; this is in contrast to dysphagia from dysmotility, in which swallowing of liquids is affected as early as, or earlier than, solids. In most instances of dysphagia, evaluation begins with fluoroscopy. Secondary studies are often endoscopic, if intrinsic obstruction is suspected; manometric, if dysmotility is suspected; and other imaging studies in particular cases. Congenital lesions may require surgery, whereas webs and peptic strictures may respond adequately to endoscopic (or bougie) dilation. Peptic strictures, once dilated, should prompt consideration of fundoplication for ongoing prophylaxis.

Extrinsic.

Esophageal duplication cysts comprise the most frequently encountered foregut duplications. These cysts are lined by intestinal epithelium, have a well-developed smooth muscle wall, and are attached to the normal gastrointestinal tract. Two thirds occur on the right side of the esophagus. The most common presentation is respiratory distress caused by compression of the adjacent airways. Dysphagia is a common symptom in older children. Upper gastrointestinal bleeding may occur as a result of acid-secreting gastric mucosa in the duplication wall. Neuroenteric cysts may contain glial elements and are associated with vertebral anomalies. Diagnosis is made either on barium swallow or chest CT. Treatment is surgical; laparoscopic approach to excision is possible.

Enlarged mediastinal or subcarinal lymph nodes, caused by infection (tuberculosis, histoplasmosis) or neoplasm (lymphoma), are the most common external masses that may compress the esophagus and produce obstructive symptoms. *Vascular anomalies* may also compress the esophagus; *dysphagia lusoria* is a term denoting the dysphagia produced by a developmental anomaly, which is often an aberrant right subclavian artery or right-sided or double aortic arch (see Chapter 425.1).

Intrinsic.

Intrinsic narrowing of the esophageal lumen may be congenital or acquired. The etiology is suggested by the location, the character of the lesion, and the clinical situation. The lower esophagus is the most common location for *peptic strictures*, which are generally somewhat ragged and several centimeters long. *Thin membranous rings*, including the Schatzki ring at the squamocolumnar junction, may also occlude this area. In the mid esophagus, congenital narrowing may be associated with the esophageal atresia/tracheoesophageal fistula complex, in which some of the lesions may incorporate cartilage and be impossible to dilate safely; alternatively, reflux esophagitis may induce a ragged and extensive narrowing that is more proximal than the usual peptic stricture, sometimes in conjunction with hiatal hernia or Barrett esophagus. *Congenital webs or rings* may narrow the upper esophagus by a postinflammatory stricture resulting from caustic ingestion or epidermolysis bullosa or posteriorly by a cricopharyngeal “bar” in the upper esophagus.

Chapter 302 - Dysmotility

Upper Esophageal and Upper Esophageal Sphincter (UES) Dysmotility (Striated Muscle).

Cricopharyngeal achalasia signifies a failure of complete relaxation of the UES, whereas *cricopharyngeal incoordination* implies full relaxation of the UES but incoordination of the relaxation with the pharyngeal contraction. These entities are usually detected on videofluoroscopic evaluation of swallowing (sometimes accompanied by visible cricopharyngeal prominence, termed a *bar*), but often the most precise definition of the dysfunction is obtained with manometry. A self-limited form of cricopharyngeal incoordination occurs in infancy and remits spontaneously during the first year of life if nutrition is maintained despite the dysphagia. In older children, idiopathic cricopharyngeal spasm is usually treated by myotomy of the UES. It is important, however, to evaluate such children thoroughly, including cranial MRI to detect Arnold Chiari malformations, which may present in this way but are best treated by cranial, rather than esophageal, surgery. Cricopharyngeal spasm may be severe enough to produce posterior pharyngeal (Zenker) diverticulum above the obstructive sphincter, but this entity occurs rarely in children.

Systemic causes of swallowing dysfunction that may affect the oropharynx, UES, and upper esophagus include cerebral palsy, Arnold Chiari malformations, syringomyelia, bulbar palsy or cranial nerve defects (Möbius syndrome, transient infantile paralysis of the superior laryngeal nerve), transient pharyngeal muscle dysfunction, spinal muscular atrophy (including Werdnig-Hoffmann disease), muscular dystrophy, infections (botulism, tetanus, poliomyelitis, diphtheria), inflammatory and connective tissue diseases (dermatomyositis, myasthenia gravis, polyneuritis, scleroderma), and familial dysautonomia. All of these may produce dysphagia. Medications (nitrazepam and benzodiazepines) and tracheostomy can adversely affect the function of the UES and thereby produce dysphagia.

Lower Esophageal and Lower Esophageal Sphincter (LES) Dysfunction (Smooth Muscle).

Causes of dysphagia due to more distal primary esophageal dysmotility include achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive LES; all but achalasia are rarely described in children.

Achalasia is a primary esophageal motor disorder of unknown etiology characterized by loss of LES relaxation and loss of esophageal peristalsis, both contributing to a functional obstruction

of the distal esophagus. Degenerative, autoimmune, and infectious factors are possible causes. Pathologically, inflammation surrounds ganglion cells, which are decreased in number. There is selective loss of postganglionic inhibitory neurons that normally lead to sphincter relaxation, leaving postganglionic cholinergic neurons unopposed. This imbalance produces high basal LES pressures and insufficient LES relaxation. The loss of esophageal peristalsis may be a secondary phenomenon. Achalasia presents as dysphagia for solids and liquids and may be accompanied by undernutrition or respiratory symptoms; retained esophageal food may produce esophagitis. The mean age in children is 8.8 yr with a mean duration of symptoms before diagnosis of 23 mo; it is uncommon before school age. Chest radiograph shows an air-fluid level in a dilated esophagus. Barium fluoroscopy reveals a smooth tapering of the lower esophagus leading to the closed LES, resembling a “bird's beak” (Fig. 302–1). Loss of primary peristalsis in the distal esophagus with retained food and poor emptying are often present. Manometry confirms the diagnosis and reveals incomplete relaxation of a high-pressure LES during swallowing, often accompanied by nonpropulsive simultaneous contractions in the distal esophagus. The two most effective treatment options are pneumatic

Figure 302-1 Barium esophagogram of a patient with achalasia demonstrating dilated esophagus and narrowing at the lower esophageal sphincter. Note retained secretions layered on top of barium in the esophagus.

dilatation and surgical (Heller) myotomy. Surgeons often supplement a myotomy with an antireflux procedure to prevent the gastroesophageal reflux disease that otherwise often ensues when the sphincter is rendered less competent. Calcium channel blockers (e.g., nifedipine) and phosphodiesterase inhibitors offer temporary relief of dysphagia. Endoscopic injection of the LES with botulinum toxin counterbalances the selective loss of inhibitory neurotransmitters by inhibiting the release of acetylcholine from nerve terminals. Botulinum toxin is expensive; half the patients may require a repeat injection within 1 yr.

Diffuse esophageal spasm causes chest pain and dysphagia and affects adolescents and adults. It is diagnosed manometrically and may be treated with nitrates or calcium channel blocking agents.

Gastroesophageal reflux disease constitutes the most common cause of nonspecific abnormalities of esophageal motor function, probably through the effect of the esophageal inflammation on the musculature.

Chapter 303 - Hiatal Hernia

Herniation of the stomach through the esophageal hiatus may occur as a common sliding hernia, in which the gastroesophageal junction slides into the thorax, or it may be paraesophageal, in which a portion of the stomach (usually the fundus) is insinuated inside the gastroesophageal junction in the hiatus (Fig. 303–1). Sliding hernias are frequently associated with gastroesophageal reflux, especially in retarded children. The relationship to hiatal hernias in adults is unclear. Medical treatment is not directed at the hernia but at the gastroesophageal reflux.

Paraesophageal hernias may be encountered after fundoplication for gastroesophageal reflux, especially if the edges of a dilated esophageal hiatus have not been approximated. Fullness after eating and upper abdominal pain are the usual symptoms. Infarction of the herniated stomach is rare.

Figure 303-1 Types of esophageal hiatal hernia. *A*, Sliding hiatal hernia, the most common type. *B*, Paraesophageal hiatal hernia.

Chapter 304 - Gastroesophageal Reflux Disease (GERD)

GERD is the most common esophageal disorder in children of all ages. Gastroesophageal reflux (GER) signifies the retrograde movement of gastric contents across the lower esophageal sphincter (LES) into the esophagus. Although occasional episodes of reflux are physiologic, exemplified by the regurgitation of normal infants, the phenomenon becomes pathologic (GERD) in children who have episodes that are more frequent or persistent, and thus produce esophagitis or esophageal symptoms, or in those who have respiratory sequelae.

Pathophysiology.

Factors determining the esophageal manifestations of reflux include the duration of esophageal exposure (a product of the frequency and duration of reflux episodes), the causticity of the refluxate, and the susceptibility of the esophagus to damage. The LES, supported by the crura of the diaphragm at the gastroesophageal junction, together with valvelike functions of the esophagogastric junction anatomy, form the antireflux barrier. In the context of even the normal intra-abdominal pressure augmentations that occur during daily life, the frequency of reflux episodes is increased by insufficient LES tone, by abnormal frequency of LES relaxations (see later), and by hiatal herniation that prevents the LES pressure from being proportionately augmented during abdominal straining. Normal intra-abdominal pressure augmentations may be further exacerbated by straining or respiratory efforts. The duration of reflux episodes is increased by lack of swallowing (during sleep) and by defective esophageal peristalsis. Vicious cycles ensue because chronic esophagitis produces esophageal peristaltic dysfunction (low amplitude waves and propagation disturbances), decreased LES tone, and inflammatory esophageal shortening that induces hiatal herniation, all of them worsening reflux.

Transient LES relaxation (TLESR) is the major primary mechanism allowing reflux to occur. TLESRs occur independent of swallowing, reducing LES pressure to 0–2?mm?Hg (above gastric), and last more than 10?s; they appear by the 26 wk of gestation. A vagovagal reflex, composed of afferent mechanoreceptors in the proximal stomach, a brain stem pattern generator, and efferents in the LES, regulates TLESRs. Gastric distention (postprandially, or due to abnormal gastric emptying or air swallowing) is thus the main stimulus for TLESRs. Whether GERD is caused by a higher frequency of TLESRs or by a greater incidence of reflux during TLESRs is debated; both are likely in different individuals. Straining during a TLESR makes reflux more likely, as do positions that place the gastroesophageal junction below the air-fluid interface in the stomach. Other factors influencing gastric pressure-volume dynamics, such as increased movement, straining, obesity, large volume or hyperosmolar meals, and increased respiratory effort (e.g., coughing, wheezing) may have the same effect.

Epidemiology and Natural History.

Infant reflux becomes symptomatic during the first few months of life, peaking at about 4 mo and resolving in most by 12 mo and nearly all by 24 mo. Symptoms in older children tend to be chronic, waxing and waning, but completely resolving in no more than half, resembling adult patterns. A genetic predisposition as an autosomal dominant form is located on chromosome 13q14 and chromosome 9.

Clinical Manifestations.

Most of the common clinical manifestations of esophageal disease can signify the presence of GERD. Infantile reflux manifests more often with regurgitation (especially postprandially), signs of esophagitis (irritability, arching, choking, gagging, feeding aversion), and resulting failure to thrive; symptoms resolve spontaneously in the majority by 12 to 24 mo. Older children, in contrast, may have regurgitation during the preschool years; complaints of abdominal and chest pain supervene during later childhood and adolescence. Occasional children present with neck contortions designated Sandifer syndrome. The respiratory (extraesophageal) presentations are also age dependent: GERD in infants may manifest as obstructive apnea or as stridor or lower airway disease in which reflux complicates primary airway disease such as laryngomalacia or bronchopulmonary dysplasia. In contrast, airway manifestations in older children are more frequently related to asthma or to otolaryngologic disease such as laryngitis or sinusitis.

Diagnosis.

For most of the typical GERD presentations, a thorough history and physical examination suffice to reach the diagnosis initially. This initial evaluation aims to identify the pertinent positives in support of GERD and its complications and the negatives that make other diagnoses unlikely. The history may be facilitated and standardized by questionnaires (the Infant Gastroesophageal Reflux Questionnaire, the I-GERQ), which also permit quantitative scores to be evaluated for their diagnostic discrimination. Important diagnoses to consider in the evaluation of an infant or a child with chronic vomiting are milk and other food allergies, pyloric stenosis, intestinal obstruction (especially malrotation with intermittent volvulus), nonesophageal inflammatory diseases, infections, inborn errors of metabolism, hydronephrosis, increased intracranial pressure, rumination, and bulimia. Focused diagnostic testing, depending on the presentation and the differential diagnosis, may then supplement the initial examination.

Most of the esophageal tests are of some use in particular patients suspected of GERD. Contrast (usually barium) radiographic study of the esophagus and upper gastrointestinal tract is performed in children with vomiting and dysphagia to evaluate for achalasia, esophageal strictures and stenosis, hiatal hernia, and gastric outlet or intestinal obstruction (Fig 304–1). Extended esophageal pH monitoring of the distal

esophagus, no longer considered the sine qua non of a GERD diagnosis, provides a quantitative and sensitive documentation of acidic reflux episodes, the most important type of reflux episodes for pathologic reflux. The distal esophageal pH probe is placed at a level corresponding to 87% of the nares-LES distance, based on regression equations using the patient's height, by fluoroscopic visualization, or by manometric identification of the LES. Normal values of distal esophageal acid exposure (i.e., pH < 4) are generally established as less than 5–8% of the total monitored time. The most important indications for esophageal pH monitoring are to assess efficacy of acid suppression during treatment, to evaluate apneic episodes in conjunction with a pneumogram, and to evaluate atypical GERD presentations such as chronic cough, stridor, and asthma. Dual pH probes, adding a proximal esophageal probe to the standard distal one, are used in the diagnosis of extraesophageal GERD, identifying upper esophageal acid exposure times of about 1% of the total time to be threshold values for abnormality. Endoscopy allows diagnosis of erosive esophagitis and complications such as strictures or Barrett esophagus; esophageal biopsies may diagnose histologic reflux esophagitis in the absence of erosions while simultaneously eliminating allergic and infectious causes. Endoscopy is also used therapeutically to dilate reflux-induced strictures. Radionucleotide scintigraphy using technetium may demonstrate aspiration and delayed gastric emptying when these are suspected. The intraluminal impedance testing is a cumbersome test, infrequently used clinically, but can document nonacid reflux. Laryngotracheobronchoscopy evaluates for visible airway signs that are associated with extraesophageal

Figure 304-1 Barium esophagogram demonstrating free gastroesophageal reflux. Note stricture caused by peptic esophagitis. Longitudinal gastric folds above the diaphragm indicate the unusual presence of an associated hiatal hernia.

GERD, such as posterior laryngeal inflammation and vocal nodules; it may permit diagnosis of silent aspiration (during swallowing or during reflux) by bronchoalveolar lavage with subsequent quantification of lipid-laden macrophages in airway secretions. Esophageal manometry permits evaluation for dysmotility, particularly in preparation for antireflux surgery.

Empirical antireflux therapy, using a time-limited trial of high-dose proton pump inhibitor (PPI), has been demonstrated in adults to be a cost-effective strategy for diagnosis; although not formally evaluated in older children, it has also been applied to this age group. However, failure to respond to such empirical treatment, or a requirement for the treatment for prolonged periods, mandates formal diagnostic evaluation.

Management.

Conservative therapy and lifestyle modification form the foundation of GERD therapy. *Dietary measures* for infants include normalization of feeding techniques, volumes, and frequency if abnormal. Thickening of formula with a tablespoon of rice cereal per ounce of formula results in fewer regurgitation episodes, greater caloric density (30?kcal/oz), and reduced crying time, although it may not modify the number of nonregurgitant reflux episodes. A short trial of a hypoallergenic diet may be used to exclude milk or soy protein allergy before pharmacotherapy. Older children and adults should be counseled to avoid acidic foods (tomatoes, chocolate, mint) and beverages (juices, carbonated and caffeinated drinks, alcohol). Weight reduction for obese patients and elimination of smoke exposure are other crucial measures at all ages.

Positioning measures are particularly important for infants, who cannot control their positions independently. Seated position worsens infant reflux and should be avoided in infants with GERD. Esophageal pH monitoring has shown significantly more reflux episodes in infants in supine and side positions compared with the prone position, but evidence supporting the supine position to reduce the risk of sudden infant death syndrome has led the American Academy of Pediatrics and the North American Society of Pediatric Gastroenterology and Nutrition to recommend nonprone positioning during sleep. During awake periods when the infant is observed, prone position and upright carried position may be used to minimize reflux. The efficacy of positioning for older children is unclear, but some evidence suggests a benefit to left side position and head elevation during sleep. Head elevation should utilize elevation of the head of the bed, rather than excess pillows, to avoid abdominal flexion and compression that might worsen reflux.

Pharmacotherapy is directed at ameliorating the acidity of the gastric contents or at promoting its aboral movement.

Antacids are the most commonly used antireflux therapy and are readily available over-the-counter. They provide rapid but transient relief of symptoms by acid neutralization. The long-term regular use of antacids cannot be recommended because of side effects of diarrhea (magnesium) and constipation (aluminum) and rare reports of more serious side effects of chronic use.

Histamine-2 receptor antagonists (H2RAs)—cimetidine, famotidine, nizatidine, and ranitidine—are widely used antisecretory agents and act by selective inhibition of histamine receptors on gastric parietal cells. There is a definite benefit of H2RAs in treatment of mild-to-moderate reflux esophagitis. H2RAs are recommended as first-line therapy because of their excellent overall safety profile.

Proton pump inhibitors (PPIs)—omeprazole, lansoprazole, pantoprazole, rabeprazole, and esomeprazole—provide the most potent antireflux effect by blocking the hydrogen-potassium ATPase channels of the final common pathway in gastric acid secretion. PPIs are superior to H2RAs in the treatment of severe and erosive esophagitis. Doses of omeprazole for children have been established (0.7–3.3?mg/kg/day), higher than those used in adults on a dose per weight basis.

Prokinetic agents available in the United States include metoclopramide (dopamine-2 and 5HT-3 antagonist), bethanechol (cholinergic agonist), and erythromycin (motilin receptor agonist). Most of these increase LES pressure; some improve gastric emptying or esophageal clearance. None affects the frequency of TLESRs. The available controlled trials have not demonstrated much efficacy for GERD.

Surgery, usually fundoplication, is effective therapy for intractable GERD in children, particularly those with refractory esophagitis or strictures and those at risk for significant morbidity from chronic pulmonary disease. It may be combined with a

gastrostomy for feeding or venting. The current availability of potent acid-suppressing medication mandates more rigorous analysis of the relative risks (or costs) and benefits of this relatively irreversible therapy in comparison to long-term pharmacotherapy. Some of the risks of fundoplication include a wrap that is “too tight” (producing dysphagia or gas-bloat) or “too loose” (and thus incompetent). Surgeons may choose to perform a “tight” (360°, Nissen) or “loose” (<360°, Thal, etc.) wrap or to add a gastric drainage procedure (e.g., pyloroplasty) to improve gastric emptying, based on their experience and the patient's disease. Preoperative accuracy of diagnosis of GERD and the skill of the surgeon are two of the most important predictors of successful outcome.

304.1 Complications of GERD

Esophageal: Esophagitis and Sequelae—Stricture, Barrett Esophagus, Adenocarcinoma.

Esophagitis may manifest as irritability, arching, and feeding aversion in infants; chest or epigastric pain in older children; and rarely as hematemesis, anemia, or Sandifer syndrome at any age. Prolonged and severe esophagitis leads to formation of strictures, generally located in the distal esophagus, producing dysphagia, and requiring repeated esophageal dilations and often fundoplication. Long-standing esophagitis predisposes to metaplastic transformation of the normal esophageal squamous epithelium into intestinal columnar epithelium, termed *Barrett esophagus*, a precursor of esophageal adenocarcinoma. Both Barrett esophagus and adenocarcinoma occur more in white males and in those with increased duration, frequency, and severity of reflux symptoms. This transformation thus increases with age to plateau in the 5th decade; adenocarcinoma is thus rare in childhood. Barrett esophagus warrants periodic surveillance biopsies, aggressive pharmacotherapy, and fundoplication for progressive lesions.

Nutritional.

Esophagitis and regurgitation may be severe enough to induce failure to thrive because of caloric deficits. Enteral (nasogastric or nasojejunal, or percutaneous gastric or jejunal) or parenteral feedings are sometimes required to treat such deficits.

Extraesophageal: Respiratory (“Atypical”) Presentations.

It is important to include GERD in the differential diagnosis of children with unexplained or refractory otolaryngologic and respiratory complaints. GERD may produce respiratory symptoms by direct contact of the refluxed gastric contents with the respiratory tract (aspiration or microaspiration) or by reflexive interactions between the esophagus and respiratory tract (inducing laryngeal closure or bronchospasm). Frequently, GERD and a primary respiratory disorder interact, and a vicious cycle between them worsens both diseases. Many children with these extraesophageal presentations do not have typical GERD symptoms, making the diagnosis difficult. These atypical GERD presentations require a thoughtful approach to the differential diagnosis that considers a multitude of primary otolaryngologic (infections, environmental allergies, postnasal drip, voice overuse) and pulmonary (asthma, cystic fibrosis) disorders. Therapy for the GERD must be more intense (usually incorporating a PPI) and prolonged (usually at least 3 to 6 mo). Subspecialist assistance from the perspective of the airway disease (otolaryngology, pulmonology) and the reflux disease (gastroenterology) is often warranted and useful, both for specialized diagnostic testing and for optimizing intensive management.

APNEA AND STRIDOR.

These upper airway presentations have been linked with GERD in case reports and epidemiologic studies; temporal relationships between them and reflux episodes have been demonstrated in some patients by esophageal pH probe monitoring; and a beneficial response to therapy for GERD provides further support in a number of case series. A comprehensive evaluation of 1,400 infants with apnea attributed the apnea to GERD in 50%. Apnea due to reflux is generally obstructive, owing to laryngospasm that may be conceived of as an abnormally intense protective reflex. Infants with such apnea are often provocatively positioned (supine or flexed seated), are recently fed, and show signs of obstructive apnea, with unproductive respiratory efforts. Stridor triggered by reflux generally occurs in infants anatomically predisposed toward stridor (by laryngomalacia or micrognathia). Spasmodic croup, an episodic frightening upper airway obstruction, may be an analogous condition in older children. Esophageal pH probe studies that fail to demonstrate linkage of these manifestations with reflux may not exclude reflux as a cause owing to the buffering of gastric contents by infant formula and the episodic nature of the conditions.

Reflux laryngitis and other otolaryngologic manifestations are now widely attributed to GERD. Hoarseness, voice fatigue, throat clearing, chronic cough, pharyngitis, sinusitis, otitis media, and a sensation of globus have been cited in this context. The paucity of well-controlled evaluations of the association contributes to the skepticism with which the associations may be considered. Other risk factors irritating the upper respiratory passages may predispose some patients with GERD to present predominantly with these complaints.

Asthma may co-occur with GERD in about 50% of asthmatic children, which contrasts to the prevalence of each condition independently in about 10% of children. Asthmatics who may be particularly likely to have GERD as a provocative factor are those with symptoms of reflux disease, those with refractory or steroid-dependent asthma, and those with nocturnal worsening. Endoscopic evaluation that discloses esophageal sequelae of GERD provides an impetus to embark on the aggressive (high dose and many months duration) therapy of GERD.

Dental erosions constitute the most common oral lesion of GERD, the lesions being distinguished by their location on the lingual surface.

Chapter 305 - Non–GERD Esophagitis

Eosinophilic Esophagitis.

The esophageal epithelium is infiltrated by eosinophils, typically in a density exceeding 15 per high-power field. Presenting symptoms include vomiting, chest or abdominal pain, and dysphagia with occasional food impactions or strictures. Most patients are male. The mean age at diagnosis is 7 yr with the duration of symptoms of 3 yr. Patients often have atopy, associated food allergies, peripheral eosinophilia (~50% of patients), and elevated IgE levels. Endoscopically the esophagus presents a granular, furrowed, or ringed appearance; esophageal histology reveals eosinophilia. It is differentiated from GERD by its general lack of erosive esophagitis, by its greater eosinophil density, and by its refractoriness to antireflux therapies. Treatment involves elimination diets for those with proven allergies, whereas inhaled and systemic corticosteroids have been used successfully for nonresponders and for nonallergic (“primary”) eosinophilic esophagitis. Little is known about its natural history, but it seems that eosinophilic esophagitis left untreated may result in stricture formation.

Infective Esophagitis.

Uncommon, and most often afflicting immunocompromised children, infective esophagitis is caused by fungal agents, such as *Candida* and *Torulopsis glabrata*; viral agents, such as herpes simplex, cytomegalovirus, and varicella zoster; and bacterial infections, including diphtheria and tuberculosis. The typical presenting signs and symptoms are odynophagia, dysphagia, and retrosternal pain; there may also be fever, nausea, and vomiting. Esophageal candidiasis commonly, but not always, presents as concurrent oropharyngeal infection and may affect immunocompetent as well as immunocompromised children. Esophageal viral infections may also present in immunocompetent hosts as an acute febrile illness. Infectious esophagitis, like other forms of esophageal inflammation, may occasionally progress to esophageal stricture. Diagnosis of infectious esophagitis is made by endoscopy and histopathologic examination; adding polymerase chain reaction, tissue-viral culture, and immunocytochemistry enhances the diagnostic sensitivity. Treatment is with appropriate antimicrobial agents, analgesics, and antacids.

“Pill” Esophagitis.

These acute injuries are produced by contact with a damaging agent. Medications

implicated in “pill” esophagitis include tetracycline, potassium chloride, ferrous

sulfate, and nonsteroidal anti-inflammatory medications, with the tablet most often ingested at bedtime with inadequate water. This practice often produces acute discomfort followed by progressive retrosternal pain, odynophagia, and dysphagia; endoscopy shows a focal lesion often localized to one of the anatomic narrowed regions of the esophagus or to an unsuspected pathologic narrowing. Treatment is supportive; lacking much evidence, antacids, topical anesthetics, and bland or liquid diets are often used.

Chapter 306 - Esophageal Perforation

The majority of esophageal perforations in children either are from blunt trauma (automobile accidents, gunshot wounds, child abuse) or are iatrogenic. Cardiac massage, the Heimlich maneuver, nasogastric tube placement, traumatic laryngoscopy or endotracheal intubation, excessively vigorous postpartum suctioning of the airway during neonatal resuscitation, difficult upper endoscopy, sclerotherapy of esophageal varices, esophageal compression by a cuffed endotracheal tube, and pneumatic dilatation for therapy of achalasia have all been implicated. Esophageal rupture has also followed forceful vomiting in patients with anorexia or caustic ingestion.

Spontaneous esophageal rupture *(Boerhaave syndrome)* is less frequent and is associated with sudden increases in intraesophageal pressure wrought by situations such as vomiting, coughing, or straining at stool. In children and adults, the tear occurs on the distal left lateral esophageal wall, because the smooth muscle layer here is weakest; in neonates *(neonatal Boerhaave syndrome)*, spontaneous rupture is on the right.

Symptoms of esophageal perforation include pain, neck tenderness, dysphagia, crepitus, fever, and tachycardia; several patients with cervical perforations have displayed cold water polydipsia in an attempt to soothe pain in the throat. Perforations in the proximal thoracic esophagus tend to create signs (pneumothorax, effusions) in the left chest, whereas the signs of distal tears are more often on the right. Cervical spine and chest radiographs are frequently diagnostic, showing mediastinal widening or paracervical free air. If normal, an esophagogram utilizing water-soluble contrast media should be performed next but may miss more than one third of cervical perforations. Therefore, a negative water-soluble contrast esophagogram should be followed by a barium study, the greater density of which may better demonstrate a small defect, though with a higher risk of inflammatory mediastinitis. Endoscopy may also be useful but carries a 30% false-negative rate. CT of the chest may assist in difficult cases.

Treatment must be individualized. Although small tears and minimal mediastinal contamination may be handled conservatively with broad-spectrum antibiotics, nothing by mouth, gastric drainage, and parenteral nutrition, the majority of pediatric esophageal perforations require surgical management.

Chapter 307 - Esophageal Varices

Portal hypertension is defined as an elevation of portal venous pressure to levels 10 to 12?mm?Hg higher than pressures present in the inferior vena cava (see Chapter 348). Decompression of this hypertension through portosystemic collateral circulation via the coronary vein, in conjunction with the left gastric veins, gives rise to esophageal varices. Most esophageal varices are “uphill varices”; less commonly, those that arise in the absence of portal hypertension and with superior vena cava (SVC) obstruction are termed “downhill varices.” Their treatment is directed at the underlying cause of the SVC abnormality. Hemorrhage from esophageal varices is the major cause of morbidity and mortality due to portal hypertension. Presentation is with significant hematemesis and melena; whereas most patients have liver disease, some children with entities such as extrahepatic portal venous thrombosis may have been asymptomatic. Any child with hematemesis and splenomegaly should be presumed to have esophageal variceal bleeding until proven otherwise.

Varices occasionally may be seen on fluoroscopic barium contrast studies, but upper endoscopy is preferred because it provides definitive diagnosis as well as therapy for acute bleeding episodes via either sclerotherapy or band ligation.

Treating children with varices with prophylactic sclerotherapy with the goal of preventing an initial hemorrhage can decrease the incidence of esophageal bleeding. Treated patients are likely to bleed from congestive gastropathy, and no improvement in survival rate may be seen. Nonselective ß-blockade, such as with propranolol, has also been used in pediatrics to achieve prevention of variceal bleeding. Endoscopic variceal ligation in adults reduces the risk of first-time variceal bleeding when compared with untreated controls as well as patients treated with ß-blockade; a decrease in mortality is only noted versus the control group (see Chapter 348).

Chapter 308 - Ingestions

308.1 Foreign Bodies in the Esophagus

The majority (80%) of foreign body ingestions occur in children, most of whom are between 6 mo and 3 yr of age. Youngsters with developmental delays as well as those with psychiatric disorders are at increased risk. Coins are the most commonly ingested foreign bodies. Food impactions are less common in children than in adults and usually occur in children with an underlying structural anomaly or motility disorder, such as repair of esophageal atresia or eosinophilic esophagitis. Most esophageal foreign bodies lodge at either the level of the cricopharyngeus (upper esophageal sphincter [UES]), the aortic arch, or just superior to the diaphragm at the gastroesophageal junction (lower esophageal sphincter [LES]).

At least 30% of children with esophageal foreign bodies may be totally asymptomatic, so any history of foreign body ingestion should be taken seriously and investigated. An initial bout of choking, gagging, and coughing may be followed by excessive salivation, dysphagia, food refusal, emesis, or pain in the neck, throat, or sternal notch regions. Respiratory symptoms such as stridor, wheezing, cyanosis, or dyspnea may be encountered if the foreign body impinges on the larynx or membranous posterior tracheal wall. Cervical swelling, erythema, or crepitations point to perforation of the oropharynx or proximal esophagus.

Diagnostic evaluation of the child with a history of foreign body ingestion starts with plain anteroposterior radiographs of the neck, chest, and abdomen, along with lateral views of the neck and chest. The flat surface of a coin in the esophagus is seen on the anteroposterior view and the edge on the lateral view. The reverse is true for coins lodged in the trachea; here, the edge

is seen anteroposteriorly and the flat side is seen laterally (Fig. 308–1). Materials such as plastic, wood, glass, aluminum, and bones may be radiolucent; therefore, failure to visualize the object with plain films in a symptomatic patient warrants urgent endoscopy. Although barium contrast studies may be helpful in the occasional asymptomatic patient with negative plain films, their use is to be discouraged because of the potential of aspiration as well as making subsequent visualization and object removal more difficult.

Treatment of esophageal foreign bodies generally merits endoscopic visualization of the object and underlying mucosa and removal of the object; this therapeutic endoscopy is most conservatively done with an endotracheal tube protecting the airway. Sharp objects in the esophagus, disc button batteries, or foreign bodies associated with respiratory symptoms mandate urgent removal. Button batteries in particular must be expediently removed, because they may induce mucosal injury with as little as 1?hr of contact time and involve all esophageal layers within 4?hr. Asymptomatic blunt objects and coins lodged in the esophagus may be observed for up to 24?hr in anticipation of passage into the stomach. If there are no problems in handling secretions, meat impactions can be observed for up to 12?hr. In patients without prior esophageal surgeries, glucagon (0.05?mg/kg intravenously) may sometimes be useful in facilitating passage of distal esophageal food boluses by decreasing the LES pressure. The use of meat tenderizers or gas-forming agents may lead to perforation and are not recommended. An alternative technique for removing esophageal coins impacted for under 24?hr, performed most safely by experienced radiology personnel, consists of passage of a Foley catheter beyond the coin at fluoroscopy, inflating the balloon, and then pulling the catheter and coin back simultaneously with the patient in a prone oblique position.

Figure 308.1-1 Radiographs of a coin in the esophagus. When foreign bodies lodge in the esophagus, the flat surface of the object is seen in the anteroposterior view *(A)* and the edge is seen in the lateral view *(B)*. The reverse is true for objects in the trachea. (Courtesy of Beverley Newman, MD.)

308.2 Caustic Ingestions

Ingestion of caustic substances results in esophagitis, necrosis, perforation, and stricture formation (see Chapter 704.7). Most cases (70%) are accidental ingestions of liquid alkali substances that produce severe, deep liquefaction necrosis; drain decloggers are most common and because they are tasteless more is ingested. Acidic agents (20% of cases) are bitter, so less may be consumed; they produce coagulation necrosis and a somewhat protective thick eschar. They may produce severe gastritis, and volatile acids may result in respiratory symptoms. Caustic ingestions produce signs and symptoms such as vomiting, drooling, refusal to drink, oral burns, dysphagia, abdominal pain, and stridor. Twenty percent of patients develop esophageal strictures. Absence of oropharyngeal lesions does not exclude the possibility of significant esophagogastric injury, which may lead to perforation or stricture. The absence of symptoms is usually associated with no or minimal lesions; in contrast, hematemesis, respiratory distress, or presence of at least three symptoms predict severe lesions. An upper endoscopy is recommended as the most efficient means of rapid identification of tissue damage and must be undertaken in symptomatic children. Dilution by water or milk is recommended as acute treatment, but neutralization, induced emesis, and gastric lavage are contraindicated. Treatment depends on the severity and extent of damage. Stricture risk is increased by circumferential ulcerations, white plaques, and sloughing of the mucosa. They may require treatment with dilation, and in some severe cases surgical resection and colon or small bowel interposition are needed. Rare late cases of superimposed esophageal carcinoma are reported.

Chapter 309 - Normal Development, Structure, and Function

Robert Wyllie

Development.

The primitive gut is recognizable by the 4th wk of gestation and is composed of the foregut, midgut, and hindgut. The foregut gives rise to the upper gastrointestinal tract including the esophagus, stomach, and duodenum to the level of the insertion of the common bile duct. The midgut gives rise to the rest of the small bowel and the large bowel to the level of the mid-transverse colon. The hindgut forms the remainder of the colon and upper anal canal. The rapid growth of the midgut causes it to protrude out of the abdominal cavity through the umbilical ring during fetal development. The midgut subsequently returns to the peritoneal cavity and rotates counterclockwise until the cecum lies in the right lower quadrant. The process is normally complete by the 8th wk of gestation. The liver derives from the hepatic diverticulum that evolves into parenchymal cells, bile ducts, vascular structures, and hematopoietic and Kupffer cells. The extrahepatic bile ducts and gallbladder develop first as solid cords that canalize by the 3rd mo of gestation. The dorsal and ventral pancreatic buds grow from the foregut by the 4th wk of gestation. The two buds fuse by the 6th wk. Exocrine secretory capacity is present by the 5th mo. *Cis*-regulatory genomic sequences govern gene expression during development. Modules of *cis* sequences are linked and allow a cascade of gene regulation that controls functional development. Extrinsic factors have the capacity to influence gene expression. In the gut, several growth factors, including growth factor-ß, insulin-like growth factor, and growth factors found in human colostrum (human growth factor and epidermal growth factor) influence gene expression.

Propulsion of food down the gastrointestinal tract relies on the coordinated action of muscles in the bowel wall. The contractions are regulated by the enteric nervous system under the influence of a variety of peptides and hormones. The enteric nervous system is derived from neural crest cells that migrate in a cranial to caudal fashion. Migration of the neural crest tissue is complete by the 24th wk of gestation. Interruption of the migration results in Hirschsprung disease. Bowel motor patterns in the newborn differ from adults. Normal fasting upper gastrointestinal motility is characterized by a triphasic pattern known as the migrating motor complex. Migrating motor complexes occur less often in neonates and they have more nonmigrating phasic activity. This leads to ineffective propulsion, particularly in premature infants. Motility in the fed state consists of a series of ring contractions that spread caudad over variable distances.

Digestion and Absorption.

The wall of the stomach, small bowel, and colon consists of four layers: the mucosa, submucosa, muscularis, and serosa. Eighty-five percent of the gastric mucosa is lined by oxyntic glands that contain cells that secrete hydrochloric acid, pepsinogen, intrinsic factor, and mucous and endocrine cells that secrete peptides that have paracrine and endocrine effects. Pepsinogen is a precursor of the proteolytic enzyme pepsin, and intrinsic factor is required for the absorption of vitamin B_{12} . Pyloric glands are located in the antrum and contain gastrin-secreting cells. Acid production and gastrin levels are inversely related to each other except in pathologic secretory states. Acid secretion is low at birth but increases dramatically by 24?hr. Acid and pepsin secretion peak during the first 10 days and decrease from 10–30 days after birth. Intrinsic factor secretion rises slowly during the first 2 wk of life.

The small bowel is approximately 270?cm in length at birth in a term neonate and grows to an adult length of 450 to 550?cm by 4 yr of age. The mucosa of the small intestine is composed of villi, which are finger-like projections of the mucosa into the bowel lumen that significantly expand the absorptive surface area. The mucosal surface is further expanded by a brush border containing digestive enzymes and transport mechanisms for monosaccharides, amino acids, dipeptides and tripeptides, and fats. The cells of the villi originate in adjacent crypts and become functional as they migrate from the crypt up the villus. The small bowel mucosa is completely renewed in 4–5 days, providing a mechanism for rapid repair after injury; but in young infants or malnourished children the process may be delayed. Crypt cells also secrete fluid and electrolytes. The villi are present by 8 wk gestation in the duodenum and by 11 wk in the ileum. Disaccharidase activities are measurable at 12 wk, but lactase activity does not reach maximal levels until 36 wk. Even premature infants usually tolerate lactose-containing formulas because of carbohydrate salvage by colonic bacteria. In African and Asian people lactase levels may begin to fall at 4 yr of age leading to intolerance to mammalian milk. Mechanisms to digest and absorb protein are in place by the 20th wk of gestation including pancreatic enzymes and mucosal mechanisms to transport amino acids and dipeptides and tripeptides. Carbohydrate, protein, and fat are normally absorbed by the upper half of the small intestine; the distal segments represent a vast reserve of absorptive capacity. Most of the sodium, potassium, chloride, and water are absorbed in the small bowel. Bile salts and vitamin B_{12} are selectively absorbed in the distal ileum, and iron is absorbed in the duodenum and proximal jejunum. Intraluminal digestion depends on the exocrine pancreas. Secretin and cholecystokinin stimulate synthesis and

secretion of bicarbonate and digestive enzymes, which are released by the upper intestinal mucosa in response to various intraluminal stimuli, among them components of the diet.

Carbohydrate digestion is normally an efficient process that is completed in the distal duodenum. Starches are broken down to glucose and oligosaccharides and disaccharides by pancreatic amylase. Residual glucose polymers are broken down at the mucosal level by glucoamylase. Lactose is broken down at the brush border by lactase, forming glucose and galactose, while sucrose is broken down by sucrase isomaltase to fructose and glucose. Galactose and glucose are primarily transported into the cell by a sodium- and energy-dependent process, whereas fructose is transported by facilitated diffusion.

Proteins are hydrolyzed by pancreatic enzymes, including trypsin, chymotrypsin, elastase, and carboxypeptidases, into individual amino acids and oligopeptides. The pancreatic enzymes are secreted as proenzymes, which are activated by release of the mucosal enzyme enterokinase. Oligopeptides are further broken down at the brush border by peptidases into dipeptides and tripeptides and amino acids. Protein can enter the cell by separate noncompetitive carriers that can transport

---

individual amino acids or dipeptides and tripeptides similar to those in the renal tubule. The human gut is capable of absorbing antigenic intact proteins during the first few weeks of life because of “leaky” junctions between enterocytes. Entry of potential protein antigens through the mucosal barrier may have a role in later food- and microbe-induced symptoms.

Fat absorption occurs in two phases. Dietary triglycerides are broken down into monoglycerides and free fatty acids by pancreatic lipase and colipase. The free fatty acids are subsequently emulsified by bile acids forming micelles with phospholipids and other fat-soluble substances and are transported to the cell membrane where they are absorbed. The fats are re-esterified in the enterocyte, forming chylomicrons that are transported through the intestinal lymphatics to the thoracic duct. Medium-chain fats are absorbed more efficiently and may directly enter the cell. They are subsequently transported to the liver via the portal system. Fat absorption may be affected at any stage of the digestion and absorption process. Decreased pancreatic enzymes occur in cystic fibrosis, cholestatic liver disease leads to poor bile salt production and micelle formation, celiac disease affects mucosal surface area, abnormal chylomicron formation occurs in abetalipoproteinemia, and intestinal lymphangiectasia affects transport of the chylomicrons.

Fat absorption is less efficient in the neonate compared with adults. Premature infants may lose up to 20% of their fat calories compared with 6% or less in the adult. Decreased synthesis of bile acids and pancreatic lipase and decreased efficiency of ileal absorption are contributing factors. Fat digestion in the neonate is facilitated by lingual and gastric lipases. Bile salt–stimulated lipase in human milk augments the action of pancreatic lipase. Infants with malabsorption of fat are usually placed on formulas that have a greater percentage of medium-chain triglycerides, which are absorbed independently of bile salts.

The colon is a 75–100?cm sacculated tube due to three strips of longitudinal muscle called taenia coli that traverse its length and fold the mucosa into haustra. Haustra and taenia appear by the 12th wk of gestation. The most common motor activity in the colon is nonpropulsive rhythmic segmentation that acts to mix the chyme and expose the contents to the colonic mucosa. Mass movement within the colon typically occurs after a meal. The colon extracts additional water and electrolytes from the luminal contents to render the stools partially or completely solid. The colon also acts to scavenge byproducts of bacterial degradation of carbohydrates. Stool is stored in the rectum until distention triggers a defecation reflex that, when assisted by voluntary relaxation of the external sphincter, permits evacuation.

Chapter 310 - Pyloric Stenosis and Congenital Anomalies of the Stomach

Robert Wyllie

The hallmark of gastric obstruction is nonbilious vomiting. Other symptoms include abdominal pain and nausea. Signs of gastric outlet obstruction include abdominal distention and bleeding from secondary inflammation of the gastric or esophageal mucosa.

The most common cause of nonbilious vomiting is infantile hypertrophic pyloric stenosis. Similar symptoms may be associated with various other gastric malformations, including pyloric atresia, antral webs, gastric duplications, and gastric volvulus. The differential diagnosis includes gastroesophageal reflux, peptic ulcer disease, salt-wasting adrenogenital syndrome, eosinophilic gastroenteritis, bezoars, and various other metabolic and motility abnormalities.

310.1 Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis occurs in approximately 3 in 1,000 infants in the United States; its frequency may be increasing. It is more common in whites of northern European ancestry, less common in blacks, and rare in Asians. Males (especially firstborns) are affected approximately four times as often as females. The offspring of a mother and to a lesser extent the father who had pyloric stenosis are at higher risk for pyloric stenosis. Pyloric stenosis develops in approximately 20% of the male and 10% of the female descendants of a mother who had pyloric stenosis. The incidence of pyloric stenosis is increased in infants with type B and O blood groups. Pyloric stenosis is associated with other congenital defects, including tracheoesophageal fistula.

Etiology.

The cause of pyloric stenosis is unknown, but many factors have been implicated. Pyloric stenosis is usually not present at birth and is more concordant in monozygotic than dizygotic twins. Abnormal muscle innervation has been implicated. In addition, elevated serum levels of prostaglandins, reduced levels of pyloric nitric oxide synthase, and infant hypergastrinemia have been found. It is unusual in stillbirths and probably develops after birth. Pyloric stenosis has been associated with eosinophilic gastroenteritis, Apert syndrome, Zellweger syndrome, trisomy 18, Smith-Lemli-Opitz syndrome, and Cornelia de Lange syndrome. There is an association between the use of erythromycin in neonates, which is administered for pertussis postexposure prophylaxis and pyloric stenosis. Erythromycin is a motilin agonist and at doses used as an antibiotic can result in strong, nonpropagated contractions that may lead to hypertrophy of the pylorus. Intravenous prostaglandins may be associated with the development of pyloric obstruction.

Clinical Manifestations.

Nonbilious vomiting is the initial symptom of pyloric stenosis. The vomiting may or may not be projectile initially but is usually progressive, occurring immediately after a feeding. Emesis may follow each feeding, or it may be intermittent. The vomiting usually starts after 3 wk of age, but symptoms may develop as early as the 1st wk of life and as late as the 5th mo. After vomiting, the infant is hungry and wants to feed again. As vomiting continues, a progressive loss of fluid, hydrogen ion, and chloride leads to hypochloremic metabolic alkalosis. Serum potassium levels are usually maintained, but there may be a total body potassium deficit. Greater awareness of pyloric stenosis has led to earlier identification of patients with fewer instances of chronic malnutrition and severe dehydration.

Jaundice associated with a decreased level of glucuronyl transferase is seen in approximately 5% of affected infants. The indirect hyperbilirubinemia usually resolves promptly after relief of the obstruction.

The *diagnosis* has traditionally been established by palpating the pyloric mass. The mass is firm, movable, approximately 2?cm in length, olive shaped, hard, best palpated from the left side, and located above and to the right of the umbilicus in the mid epigastrium beneath the liver edge. In healthy infants, feeding can be an aid to the diagnosis. After feeding, there may be a visible gastric peristaltic wave that progresses across the abdomen (Fig. 310–1). After the infant vomits, the abdominal musculature is more relaxed and the “olive” easier to palpate. Sedation may be used to facilitate examination but is usually unnecessary. The diagnosis can be established clinically 60–80% of the time by an experienced examiner.

Ultrasound examination confirms the diagnosis in the majority of cases, allowing an earlier diagnosis in infants with

Figure 310.1-1 Gastric peristaltic wave in an infant with pyloric stenosis.

suspected disease but no pyloric mass on physical examination. Criteria for diagnosis include pyloric thickness greater than 4?mm or an overall pyloric length greater than 14?mm (Fig. 310–2). Ultrasonography has a sensitivity of approximately 95%. When barium studies are performed, they demonstrate an elongated pyloric channel, a bulge of the pyloric muscle into the antrum (shoulder sign), and parallel streaks of barium seen in the narrowed channel, producing a “double tract sign” (Fig. 310–3).

Figure 310.1-2 *A*, Transverse sonogram demonstrating a pyloric muscle wall thickness of greater than 4?mm (*distance between crosses*). *B*, Horizontal image demonstrating a pyloric channel length greater than 14?mm (*wall thickness outlined between crosses*) in an infant with pyloric stenosis.

Differential Diagnosis.

The usual patient can be diagnosed by the characteristic clinical pattern and the identification of a pyloric mass on physical examination or ultrasonography. Infants who are exceptionally reactive to external stimuli, those fed by inexperienced or anxious caretakers, or those for whom an adequate maternal-infant bonding relationship has not been established may vomit frequently in the early weeks of life. Such infants may come to resemble infants with pyloric stenosis; the vomiting may be persistent and even projectile. Gastric waves are occasionally visible in small, emaciated infants who do not have pyloric stenosis. Infrequently, gastroesophageal reflux, with or without a hiatal hernia, may be confused with pyloric stenosis. Gastroesophageal reflux disease can be differentiated from pyloric stenosis by radiographic studies. Adrenal insufficiency may simulate pyloric stenosis, but the absence of a metabolic acidosis and elevated serum potassium and urinary sodium concentrations of adrenal insufficiency aid in differentiation. Inborn errors of metabolism may produce recurrent emesis with alkalosis (urea cycle) or acidosis (organic acidemia) and lethargy, coma, or seizures. Vomiting with diarrhea suggests gastroenteritis, but patients with pyloric stenosis occasionally have diarrhea. Very rarely, a pyloric membrane or pyloric duplication may result in projectile vomiting, visible peristalsis, and, in the case of a duplication, a palpable mass. Duodenal stenosis proximal to the ampulla of Vater results in the clinical features of pyloric stenosis but can be differentiated by the presence of a pyloric mass on physical examination or ultrasonography.

Treatment.

The preoperative treatment is directed toward correcting the fluid, acid-base, and electrolyte losses. Intravenous fluid therapy is begun with 0.45–0.9% saline, in 5–10% dextrose, with the addition of potassium chloride in concentrations of 30–50?mEq/L. Fluid therapy should be continued until the infant is rehydrated and the serum bicarbonate concentration is less than 30?mEq/dL, which implies that the alkalosis has been corrected. Correction of the alkalosis is essential to prevent postoperative apnea, which may be associated with anesthesia. Most

Figure 310.1-3 Barium in the stomach of an infant with projectile vomiting. The attenuated pyloric canal is typical of congenital hypertrophic pyloric stenosis.

infants can be successfully rehydrated within 24?hr. Vomiting usually stops when the stomach is empty, and only an occasional infant requires nasogastric suction.

The surgical procedure of choice is the Ramstedt pyloromyotomy. The procedure is performed through a short transverse incision or laparoscopically. The underlying pyloric mass is split without cutting the mucosa, and the incision is closed. Postoperative vomiting may occur in half the infants and is thought to be secondary to edema of the pylorus at the incision site. In most infants, however, feedings can be initiated within 12–24?hr after surgery and advanced to maintenance oral feedings within 36–48?hr of the surgery. Persistent vomiting suggests an incomplete pyloromyotomy, gastritis, gastroesophageal reflux disease, or another cause of the obstruction.

The surgical treatment of pyloric stenosis is curative, with an operative mortality of 0–0.5%. Conservative medical therapy (small frequent feedings, atropine) has been attempted in the past but is associated with slow improvement and a higher mortality. Endoscopic balloon dilation has been successful in infants with persistent vomiting secondary to incomplete pyloromyotomy.

310.2 Congenital Gastric Outlet Obstruction

Gastric outlet obstruction resulting from pyloric atresia and antral webs is uncommon and accounts for less than 1% of all the atresias and diaphragms of the alimentary tract. The cause of the defects is unknown. Pyloric atresia has been associated with epidermolysis bullosa and usually presents in early infancy. The sex distribution is equal.

Clinical Manifestations.

Infants with pyloric atresia present with nonbilious vomiting, feeding difficulties, and abdominal distention during the 1st day of life. Polyhydramnios occurs in the majority of cases, and low birthweight is common. Rupture of the stomach may occur as early as the 1st 12?hr of life. Infants with antral web may present with less dramatic symptoms, depending on the degree of obstruction. Older children with antral webs present with nausea, vomiting, abdominal pain, and weight loss.

Diagnosis.

The diagnosis of congenital gastric outlet obstruction is suggested by the finding of a large, dilated stomach on abdominal plain radiographs. Upper gastrointestinal contrast series is usually diagnostic and demonstrates a pyloric dimple. An antral web may appear as a thin septum near the pyloric channel. In older children, endoscopy has been helpful in identifying antral webs.

Treatment.

The treatment of gastric outlet obstruction in neonates starts with the correction of dehydration and hypochloremic alkalosis. Persistent vomiting should be relieved with nasogastric decompression. Surgical or endoscopic repair should be undertaken when a patient is stable.

310.3 Gastric Duplication

Gastric duplications are uncommon cystic or tubular structures that usually occur

within the wall of the stomach. Most are smaller than 12?cm in diameter and do not usually communicate with the stomach lumen. Associated anomalies occur in as many as 35% of patients. Duplications have been attributed to a failure of recanalization after the solid stage of intestinal development.

The most common *clinical manifestations* are associated with partial or complete gastric outlet obstruction. In 33% of patients, the cyst may be palpable. Communicating duplications may cause gastric ulceration and be associated with hematemesis or melena.

Gastric duplications are visualized on upper gastrointestinal series as an extrinsic defect usually located along the lesser curve of the stomach. CT or ultrasonography may be helpful in defining a cystic structure. Surgical excision is the treatment for symptomatic gastric duplications.

310.4 Gastric Volvulus

Gastric volvulus presents as a triad of a sudden onset of severe epigastric pain, intractable retching with emesis, and inability to pass a tube into the stomach. The stomach is tethered longitudinally by the gastrohepatic, gastrosplenic, and gastrocolic ligaments. In the transverse axis, it is tethered by the gastrophrenic ligament and the retroperitoneal attachment of the duodenum. A volvulus occurs when one of these attachments is absent or stretched, allowing the stomach to rotate around itself. In most children, other associated defects are present, including intestinal malrotation, diaphragmatic defects, or asplenia. Volvulus may occur along the longitudinal axis, producing organoaxial volvulus, or along the transverse axis, producing mesenteroaxial volvulus.

Clinical Manifestations.

The clinical presentation of gastric volvulus is nonspecific and suggests high intestinal obstruction. Gastric volvulus in infancy is usually associated with nonbilious vomiting. Acute volvulus may advance rapidly to strangulation and perforation. Chronic gastric volvulus is more common in older children; the children present with a history of emesis, abdominal pain, and early satiety.

The *diagnosis* is suggested in plain abdominal radiographs by the presence of a dilated stomach. Erect abdominal films demonstrate a double fluid level with a characteristic “beak” near the lower esophageal junction in mesenteroaxial volvulus. In organoaxial volvulus, a single air-fluid level is seen without the characteristic beak. *Treatment* of acute gastric volvulus is emergent surgery once a patient is stabilized. In selected cases of chronic volvulus in older patients, endoscopic correction has been successful.

310.5 Hypertrophic Gastropathy

Hypertrophic gastropathy in children is uncommon and, in contrast to that in adults (Ménétrier disease), is usually a transient,

benign, self-limited condition, possibly initiated by an infectious agent (cytomegalovirus, herpes simplex virus, *Giardia, Helicobacter pylori*). Clinical manifestations include vomiting, anorexia, upper abdominal pain, diarrhea, edema (hypoproteinemic protein-losing enteropathy), ascites, and, rarely, hematemesis if ulceration occurs. Endoscopy with biopsy confirms the diagnosis. The mean age at diagnosis is 5 yr (range: 2 days–17 yr); the illness usually lasts 2–4 wk, with complete resolution the rule. The differential diagnosis includes eosinophilic gastroenteritis, gastric lymphoma or carcinoma, Crohn disease, and inflammatory pseudotumor. **REFERENCES**

Chapter 311 - Intestinal Atresia, Stenosis, and Malrotation

Robert Wyllie

General Considerations.

Intestinal obstruction occurs in approximately 1 in 1,500 live births. Obstruction may be partial or complete and may arise from intrinsic or extrinsic abnormalities of the gut. Obstruction can be further classified as simple or strangulating. Simple obstruction is associated with the failure of progression of aboral flow of luminal contents. Strangulating obstruction is associated with impaired blood flow to the intestine in addition to obstruction of the flow of luminal contents. If strangulating obstruction is not promptly relieved, it may lead to bowel infarction and perforation.

Obstruction is typically associated with an accumulation of ingested food, gas, and intestinal secretions proximal to the point of obstruction, leading to distention of the bowel. As the bowel dilates, intestinal absorption decreases and secretion of fluid and electrolytes increases. The shift in fluid and electrolytes results in isotonic intravascular depletion usually associated with hypokalemia. The gut proximal to the obstruction initially demonstrates an increase in contractile activity, which is followed by a marked decrease with hypoactive bowel sounds. The combination of fluid accumulation and hypomotility is associated with nausea and vomiting.

Congenital obstructive lesions of the intestines can be viewed as *intrinsic* (e.g., atresia, stenosis, meconium ileus, and aganglionic megacolon) or *extrinsic* (e.g., malrotation, constricting bands, intra-abdominal hernias, and duplications). An attempt should be made to locate the lesion preoperatively to guide the surgical approach.

When the obstruction is *complete,* there should be little difficulty in clinical recognition, but when it is *incomplete,* diagnosis may pose considerable difficulty. Polyhydramnios frequently accompanies high intestinal obstruction, as it does in esophageal atresia. When polyhydramnios has been noted, the infant's stomach should be aspirated immediately after birth. Aspiration of 15–20?mL or more of gastric fluid, especially if it is bile stained, is suggestive of a high intestinal obstruction.

Meconium stools may be passed initially if the obstruction is in the upper part of the small intestine or if the obstruction developed late in intrauterine life.

When obstruction is *incomplete* (e.g., as with intestinal stenosis, constricting bands, duplications, and incomplete volvulus), signs (vomiting, abdominal distention, obstipation) may appear shortly after birth or may be delayed an indeterminate time. They may approach in severity those of a completely obstructive lesion, or they may be sufficiently mild and infrequent as to be overlooked until either an acute episode or diagnostic studies disclose the lesion.

Atresia refers to complete obstruction of the bowel lumen, and stenosis refers to a partial block of luminal contents. Intestinal atresia is common in the duodenum, jejunum, and ileum and rare in the colon. Intestinal atresia accounts for approximately 33% of all cases of neonatal intestinal obstruction. Atresias affect males and females equally.

Blood flow to the obstructed bowel decreases as the bowel dilates. Blood flow is shifted away from the mucosa, with loss of mucosal integrity. Bacteria proliferate in the stagnant bowel, with a predominance of coliforms and anaerobes. The rapid proliferation of bacteria coupled with the loss of mucosal integrity allows bacterial translocation across the bowel wall, resulting in endotoxemia, bacteremia, and sepsis.

The *clinical presentation* of intestinal obstruction varies with the cause, level of obstruction, and time between the obstructing event and the patient's evaluation. The classic symptoms of obstruction include nausea and vomiting, abdominal distention, and obstipation. Obstruction high in the intestinal tract involving the duodenum or proximal jejunum results in large-volume, frequent, bilious emesis. Pain is intermittent and is usually relieved by vomiting. The pain is localized to the epigastrium or periumbilical area, and there is little abdominal distention. Obstruction in the distal small bowel leads to moderate or marked abdominal distention with emesis that is progressively feculent. Pain is usually diffuse over the entire abdomen.

No laboratory studies are diagnostic of obstruction or differentiate simple obstruction from obstruction associated with bowel infarction. Obstruction high in the gastrointestinal tract is often associated with hypochloremic metabolic alkalosis. Marked leukocytosis with or without thrombocytopenia, metabolic acidosis, and hematochezia suggests bowel infarction. Serum amylase and lipase determinations should be performed to rule out pancreatitis.

Bowel obstruction is usually suggested on the basis of history and physical examination. Imaging is used to confirm the diagnosis and localize the area of obstruction. Plain supine and erect or decubitus radiographs are the initial studies.

Valuable information on the location of congenital obstructive lesions in the intestine may often be obtained from flat and upright radiographs of the abdomen taken without use of contrast media. With completely obstructing lesions, distention of the bowel is noted above the obstruction and a series of fluid levels with superimposed gas in the distended loops may be observed in the upright or cross-table lateral position. Pneumoperitoneum may be seen if there is a perforation with free air in the

subphrenic regions or over the liver in the left lateral decubitus position. Calcification within the peritoneal cavity usually indicates meconium peritonitis. Rarely, obstruction with intraluminal calcification may be associated with rectourinary fistula, colonic aganglionosis, or intestinal atresia. A characteristic ground-glass appearance in the right lower quadrant with trapped bubbles of air within the obstructing meconium may be seen in patients with meconium ileus. Air is usually demonstrable radiographically in the stomach of a normal infant immediately after birth; within 1?hr air may reach the proximal portion of the small intestine and segments of the colon; air may become visible in the distal parts of the colon as early as the 3rd hr or as late as 18?hr. It is difficult to accurately differentiate small from large bowel obstruction in children younger than 2 yr.

Ultrasonography is helpful in identifying pyloric stenosis, malrotation, and volvulus or intussusception and in differentiating pyloric stenosis from other causes of proximal obstruction. Contrast studies of the bowel are indicated when plain films or sonograms fail to identify the source of obstruction. Water-soluble contrast studies avoid the risk of barium contamination of the peritoneum when there is a significant chance of perforation not detected by the presence of pneumoperitoneum on plain films. Water-soluble contrast enemas are useful in diagnosing malrotation, meconium ileus, meconium plug, and intussusception. In meconium ileus, meconium plug, and intussusception the enema may be diagnostic and relieve the obstruction. Oral or nasogastric contrast medium is used to identify obstructing lesions in the proximal bowel (atresia, volvulus, malrotation). Water-soluble agents are used if perforation is suspected.

Management.

Infants and children with bowel obstruction have mechanical obstruction and loss of fluid and electrolytes. Those with strangulating vascular obstruction may also develop intestinal ischemia with sepsis and shock. Initial treatment must be directed at fluid resuscitation and stabilizing the patient. Nasogastric decompression usually provides relief of pain and vomiting. After appropriate cultures, broad-spectrum antibiotics are usually started in neonates with bowel obstruction and those with suspected strangulating infarction. Patients with strangulation must have immediate surgical relief before the bowel infarcts, resulting in gangrene and intestinal perforation. Extensive intestinal necrosis results in short-gut syndrome (see Chapter 320.7). Nonoperative conservative management is usually limited to children with suspected adhesions or inflammatory strictures that may resolve with nasogastric decompression or anti-inflammatory medications. If clinical signs of improvement are not evident within 12–24?hr, then operative intervention is usually indicated.

311.1 Duodenal Obstruction

Duodenal atresia is thought to arise from failure to recanalize the lumen after the solid phase of intestinal development during the 4th and 5th wk of gestation. The incidence of duodenal atresia is 1 in 10,000 births and accounts for 25–40% of all intestinal atresias. Half the patients are born prematurely. Duodenal atresia may take several forms, including an intact membrane obstructing the lumen, a short fibrous cord connecting two blind duodenal pouches, or a gap between the nonconnecting ends of the duodenum. An unusual cause of obstruction is a “windsock” web, which is a distensible flap of tissue associated with anomalies of the biliary tract. The membranous form of atresia is most common, with obstruction occurring distal to the ampulla of Vater in the majority of patients. Duodenal obstruction may also be a result of an extrinsic compression such as an annular pancreas or from Ladd bands in patients with malrotation. Down syndrome occurs in 20–30% of patients with duodenal atresia. Other congenital anomalies that are associated with duodenal atresia include malrotation (20%), esophageal atresia (10–20%), congenital heart disease (10–15%), and anorectal and renal anomalies (5%).

Clinical Manifestations.

The hallmark of duodenal obstruction is bilious vomiting without abdominal distention, which is usually noted on the 1st day of life. Peristaltic waves may be visualized early in the disease process. A history of polyhydramnios is present in half the pregnancies and is caused by a failure of absorption of amniotic fluid in the distal intestine. Jaundice is present in one third of the infants. The diagnosis is suggested by the presence of a “double-bubble sign” on plain abdominal radiographs (Fig. 311–1). The appearance is caused by a distended and gas-filled stomach and proximal duodenum. Contrast

Figure 311.1-1 Abdominal radiograph of a newborn infant held upright. Note the “double bubble” gas shadow above and the absence of gas in the distal bowel in this case of congenital duodenal atresia.

studies are usually not necessary and may be associated with aspiration if attempted. Contrast studies may occasionally be needed to exclude malrotation and volvulus because intestinal infarction may occur within 6–12?hr if the volvulus is not relieved. Prenatal diagnosis of duodenal atresia is readily detected by fetal ultrasonography.

Treatment.

The initial treatment of infants with duodenal atresia includes nasogastric or orogastric decompression with intravenous fluid replacement. Echocardiogram and radiology of the chest and spine should be performed to evaluate for associated anomalies. Approximately one third of infants with duodenal atresia have associated life-threatening congenital anomalies. Definitive correction of duodenal atresia is usually postponed to evaluate and treat these life-threatening anomalies.

The usual surgical repair for duodenal atresia is duodenoduodenostomy. The dilated proximal bowel may be tapered in an attempt to improve peristalsis. A gastrostomy tube may be placed to drain the stomach and protect the airway. Intravenous nutritional support or a transanastomotic jejunal tube is needed until infants start to feed orally. The prognosis is primarily dependent on the presence of associated anomalies.

If obstruction is due to Ladd bands with malrotation, an operation is necessary without delay. After division of the abnormal peritoneal folds or bands, the entire large intestine is placed within the left side of the abdomen, after first removing the

appendix, with the small bowel on the right—the fetal position of nonrotation. Appendectomy is performed to avoid later misdiagnosis of appendicitis. Malrotation may also coexist with an intrinsic duodenal obstruction, such as a membrane or stenosis;

---

this may be identified by passing a balloon-tipped catheter into the jejunum below the site of obstruction, inflating the balloon, and slowly withdrawing the catheter. Annular pancreas is best treated by duodenoduodenostomy without dividing the pancreas, leaving as short a defunctioned loop as possible. Duodenal diaphragmatic obstruction is managed by duodenoplasty. The possibility exists that the common bile duct may open on the diaphragm itself.

311.2 Jejunal and Ileal Atresia and Obstruction

Jejunoileal atresias have been attributed to intrauterine vascular accidents leading to ischemic necrosis of the sterile bowel and resorption of the affected segments. Four different types of jejunal and ileal atresia are encountered (Fig. 311–2). Type I accounts for 20% of the atresias and is an intraluminal diaphragm that obstructs the lumen while continuity is maintained between the proximal and distal bowel. In type II, a small-diameter solid cord connects the proximal and distal bowel, accounting for about 35% of defects. Type III is divided into two subtypes. Type IIIa accounts for approximately 35% of all atresias and occurs when both ends of the bowel end in blind loops accompanied by a small mesenteric defect. Type IIIb is associated with an extensive mesenteric defect and a loss of the normal blood supply to the distal bowel. The distal ileum coils around the ileocolic artery, from which it derives its entire blood supply, producing an “apple-peel” appearance. This anomaly is associated with prematurity, an unusually short distal ileum, and significant foreshortening of the bowel. Type IV is multiple segments of bowel atresia and accounts for approximately 5% of all bowel atresias. Colon atresia has similarities to jejunoileal atresia but is much less common.

Figure 311.2-2 *A* and *B*, Classification of intestinal atresia. Type I: Mucosal obstruction caused by an intraluminal membrane with intact bowel wall and mesentery. Type II: Blind ends are separated by a fibrous cord. Type IIIa: Blind ends are separated by a V-shaped mesenteric defect. Type IIIb: “Apple peel” appearance. Type IV: Multiple atresias. (From Grosfeld J: Jejunoileal atresia and stenosis. In Welch KJ, et al [editors]: *Pediatric Surgery*, 4th ed. Chicago, Year Book Medical Publishers, 1986.)

Meconium ileus occurs primarily in newborn infants with cystic fibrosis. Approximately 10% of infants with cystic fibrosis will develop meconium ileus; 80–90% of infants presenting with meconium ileus have cystic fibrosis. *In simple meconium ileus,* the last 20–30?cm of ileum is collapsed and filled with pellets of pale-colored stool, above which a dilated loop of varying length appears obstructed by meconium with the consistency of thick syrup or glue. Peristalsis fails to propel this very viscid material forward, and it becomes impacted in the ileum. Volvulus, atresia, or perforation of the bowel accompanies *complicated* meconium ileus. Perforation in utero produces meconium peritonitis. Intraperitoneal meconium can cause dense adhesions, leading postnatally to adhesive intestinal obstruction, and may rapidly become calcified.

In 5% of patients with *Hirschsprung disease,* the aganglionic segment involves not only the entire colon but also terminal ileum. This condition causes a dilated small intestine with ganglionated but somewhat hypertrophied walls, a funnel-shaped transitional hypoganglionic zone, and a collapsed distal aganglionic bowel.

Clinical Manifestation.

In contrast to duodenal atresia, extragastrointestinal anomalies are less common in atresias of the distal intestine. The diagnosis of jejunoileal atresia may be made by prenatal ultrasonograms. Polyhydramnios occurs in 25% of affected patients. Monozygotic twins are at higher risk for atresias than are dizygotic twins or singletons. Premature birth occurs in one third of infants. Most infants become symptomatic during the 1st day of life with abdominal distention and bile-stained emesis or gastric aspirate. Sixty to 75% of the infants fail to pass meconium. Jaundice has been found in 20–30% of the patients. Plain radiographs demonstrate many air-fluid levels or peritoneal calcification associated with meconium peritonitis. Contrast studies of the upper and lower bowel can delineate the level of obstruction and differentiate atresia from meconium ileus, meconium plug, and Hirschsprung disease. Abdominal ultrasound can distinguish meconium ileus from ileal atresia and identify intestinal malrotation.

In meconium ileus, plain films of the abdomen show a typical hazy or ground-glass appearance in the right lower quadrant. Small bubbles of gas trapped in meconium are dispersed within this area (see Chapter 91.1). Furthermore, owing to their viscid contents, moderately dilated loops of bowel do not have the air-fluid levels usually seen radiographically on the erect projection. If there is meconium peritonitis, patchy calcification may be noted, usually in the flanks. Pneumoperitoneum is most readily seen as free air between the liver and the diaphragm on an upright radiograph of the abdomen; if there is a large amount of free air, the entire abdomen may look like a football from distention with air; the ligamentum teres is sometimes clearly visible in the midline.

It is impossible to consistently distinguish small bowel from large bowel by studying plain radiographs of the abdomen in newborns and infants. If plain radiographs are nonspecific, a water-soluble contrast (Gastrografin, Hypaque) study of the colon may be needed to distinguish small from large intestine obstructions. A small colon, “microcolon,” suggests disuse and the presence of obstruction proximal to the ileocecal valve. Water-soluble enemas should be used with caution in the diagnosis and treatment of meconium ileus because their hyperosmolality may result in dehydration; the enema pressure may result in perforation.

Treatment.

Patients with small bowel obstruction should be stable and in adequate fluid and electrolyte balance before operation or radiographic attempts at disimpaction unless volvulus is suspected. Infections should be treated with appropriate antibiotics. Prophylactic antibiotics are usually given before surgery.

Ileal or jejunal atresia requires resection of the dilated proximal portion of the bowel

followed by end-to-end anastomosis. If

a simple mucosal diaphragm is present, jejunoplasty or ileoplasty with partial excision of the web is an acceptable alternative to resection. In uncomplicated meconium ileus Gastrografin enemas will diagnose the obstruction and wash out the inspissated material. Gastrografin is hypertonic and care must be taken to avoid dehydration, shock, and bowel perforation. The enema may have to be repeated after 8–12?hr. Resection after reduction is not needed if there have been no ischemic complications.

About 50% of patients with simple meconium ileus do not adequately respond to water-soluble enemas and need laparotomy. Operative management is indicated when the obstruction cannot be relieved by repeated attempts at nonoperative management and for infants with complicated meconium ileus. The extent of surgical intervention depends on the degree of pathology. In simple meconium ileus, the plug can be relieved by manipulation or direct enteral irrigation with *N*-acetylcysteine following an enterotomy. In complicated cases, bowel resection, peritoneal lavage, abdominal drainage, and stoma formation may be necessary. Total parenteral nutrition will be required.

311.3 Malrotation

Malrotation is incomplete rotation of the intestine during fetal development. The gut starts as a straight tube from stomach to rectum. The midbowel (distal duodenum to midtransverse colon) begins to elongate and progressively protrudes into the umbilical cord until it lies totally outside the confines of the abdominal cavity. As the developing bowel rotates in and out of the abdominal cavity, the superior mesenteric artery, which supplies blood to this section of gut, acts as an axis. The duodenum, on re-entering the abdominal cavity, moves to the region of the ligament of Treitz, and the colon that follows is directed to the left upper quadrant. The cecum subsequently rotates counterclockwise within the abdominal cavity and comes to lie in the right lower quadrant. The duodenum becomes fixed to the posterior abdominal wall before the colon is completely rotated. After rotation, the right and left colon and the mesenteric root become fixed to the posterior abdomen. These attachments provide a broad base of support to the mesentery and the superior mesenteric artery, thus preventing twisting of the mesenteric root and kinking of the vascular supply. Abdominal rotation and attachment are completed by 3 mo gestation.

Nonrotation occurs when the bowel fails to rotate after it returns to the abdominal cavity. The first and second portions of the duodenum are in their normal position, but the remainder of the duodenum, jejunum, and ileum occupy the right side of the abdomen while the colon is located on the left. Malrotation and nonrotation are associated with abdominal heterotaxia and the asplenia-polysplenia congenital heart malformation syndrome anomalad (see Chapter 424.11).

The most common type of malrotation involves failure of the cecum to move into the right lower quadrant (Fig. 311–3). The usual location of the cecum is in the subhepatic area. Failure of the cecum to rotate properly is associated with failure to form the normal broad-based adherence to the posterior abdominal wall. The mesentery including the superior mesenteric artery is tethered by a narrow stalk, which may twist around itself, producing a midgut volvulus. In addition, bands of tissue (Ladd bands) may extend from the cecum to the right upper quadrant, crossing and possibly obstructing the duodenum.

Clinical Manifestation.

The majority of patients present within the 1st yr of life with symptoms of acute or chronic obstruction. Infants often present within the 1st wk of life with bilious emesis and acute bowel obstruction. Older infants present with episodes of recurrent abdominal pain that may mimic colic. Malrotation in older children may present with recurrent episodes of vomiting, abdominal pain, or both. Patients

Figure 311.3-3 The mechanism of intestinal obstruction with incomplete rotation of the midgut (malrotation). The *dotted lines* show the course the cecum should have taken. Failure to rotate has left obstructing bands across the duodenum and a narrow pedicle for the midgut loop, making it susceptible to volvulus. (From Nixon HH, O'Donnell B: *The Essentials of Pediatric Surgery*. Philadelphia, JB Lippincott, 1961.)

occasionally present with malabsorption or protein-losing enteropathy associated with bacterial overgrowth. Symptoms are caused by intermittent volvulus or duodenal compression by Ladd bands or other adhesive bands affecting the small and large bowel. Twenty-five to 50% of adolescents with malrotation are asymptomatic. Adolescents who become symptomatic present with acute intestinal obstruction or history of recurrent episodes of abdominal pain with less frequent vomiting and diarrhea. Patients of any age with a rotational anomaly can develop volvulus without pre-existing symptoms.

An acute presentation of small bowel obstruction in a patient without previous bowel surgery is usually a result of volvulus associated with malrotation. This is a life-threatening complication of malrotation and the main reason that symptoms suggestive of malrotation should be investigated. The diagnosis is by ultrasound or contrast radiographic studies. The abdominal plain film is usually nonspecific but may demonstrate evidence of duodenal obstruction with a double-bubble sign. Barium enema usually demonstrates malposition of the cecum but may be normal in 10% of patients. Upper gastrointestinal series demonstrates malposition of the ligament of Treitz. Ultrasonography demonstrates inversion of the superior mesenteric artery and vein. A superior mesenteric vein located to the left of the superior mesenteric artery is suggestive of malrotation. Malrotation with volvulus is suggested by duodenal obstruction, thickened bowel loops to the right of the spine, and free peritoneal fluid.

Surgical intervention is recommended for any patient with a significant rotational abnormality, regardless of age. If a volvulus is present, it is reduced and the duodenum and upper jejunum are freed of any bands and remain in the right abdominal cavity. The colon is freed of adhesions and placed in the right abdomen with the cecum in the left lower quadrant, usually accompanied by incidental appendectomy. Extensive intestinal ischemia from volvulus produces the short-gut syndrome (see Chapter 320.7). Persistent symptoms after repair of malrotation

should suggest a pseudo-obstruction–like motility disorder.

Chapter 312 - Intestinal Duplications, Meckel Diverticulum, and Other Remnants of the Omphalomesenteric Duct

Robert Wyllie

312.1 Intestinal Duplication

Duplications of the intestinal tract are rare anomalies that consist of well-formed tubular or spherical structures firmly attached to the intestine with a common blood supply. The lining of the duplications resembles that of the gastrointestinal tract. Duplications are located on the mesenteric border and may communicate with the intestinal lumen. Duplications can be classified into three categories: localized duplications, duplications associated with spinal cord defects and vertebral malformations, and duplications of the colon. Occasionally (10–15%), multiple duplications are found.

Localized duplications may occur in any area of the gastrointestinal tract but are most common in the ileum and jejunum. They are usually cystic or tubular structures within the wall of the bowel. The cause is unknown, but their development has been attributed to defects in recanalization of the intestinal lumen after the solid stage of embryologic development. Duplication of the intestine occurring in association with vertebral and spinal cord anomalies (hemivertebra, anterior spina bifida, band connection between lesion and cervical or thoracic spine) is thought to arise from splitting of the notochord in the developing embryo. Duplication of the colon is usually associated with anomalies of the urinary tract and genitals. Duplication of the entire colon, rectum, anus, and terminal ileum may occur. The defects are thought to be secondary to caudal twinning, with duplication of the hindgut, genital, and lower urinary tracts.

Clinical Manifestations.

Symptoms depend on the size, location, and mucosal lining. Duplications may cause bowel obstruction by compressing the adjacent intestinal lumen, or they may act as the lead point of an intussusception or a site for a volvulus. If they are lined by acid-secreting mucosa, they may cause ulceration, perforation, and hemorrhage of the adjacent bowel. Patients may present with abdominal pain, vomiting, palpable mass, or acute gastrointestinal hemorrhage. Intestinal duplications in the thorax

(neuroenteric cysts) may present as respiratory distress. Duplications of the lower bowel may cause constipation or diarrhea or be associated with recurrent prolapse of the rectum.

The *diagnosis* is suspected on the basis of the history and physical examination. Radiologic studies such as barium studies, ultrasonography, CT, and MRI are helpful but usually nonspecific, demonstrating cystic structures or mass effects. Radioisotope technetium scanning may localize ectopic gastric mucosa. The *treatment* of duplications is surgical resection and management of associated defects.

312.2 Meckel Diverticulum and Other Remnants of the Omphalomesenteric Duct

A Meckel diverticulum is a remnant of the embryonic yolk sac, which may also be referred to as the omphalomesenteric duct or vitelline duct. The omphalomesenteric duct connects the yolk sac to the gut in a developing embryo and provides nutrition until the placenta is established. Between the 5th and 7th wk of gestation, the duct attenuates and separates from the intestine. Just before this involution, the epithelium of the yolk sac develops a lining similar to that of the stomach. Partial or complete failure of involution of the omphalomesenteric duct results in various residual structures. Meckel diverticulum is the most common of these structures and is the most frequent congenital gastrointestinal anomaly, occurring in 2–3% of all infants. A typical Meckel diverticulum is a 3–6?cm outpouching of the ileum along the antimesenteric border 50–75?cm from the ileocecal valve (Fig. 312–1). The distance from the ileocecal valve depends on the age of the patient. Other omphalomesenteric duct remnants occur infrequently, including a persistently patent duct, a solid cord, or a cord with a central cyst or a diverticulum associated with a persistent cord between the diverticulum and the umbilicus.

Clinical Manifestations.

Symptoms of a Meckel diverticulum usually arise within the 1st 2 yr of life, but initial symptoms are common during the 1st decade. The majority of symptomatic Meckel diverticula are lined by an ectopic mucosa, including an acid-secreting mucosa that causes intermittent painless rectal bleeding by ulceration of the adjacent normal ileal mucosa. Unlike the upper duodenal mucosa, the acid is not neutralized by pancreatic bicarbonate.

The stool is typically described as brick colored or currant jelly colored. Bleeding may cause significant anemia but is usually self-limited because of contraction of the splanchnic vessels, as patients become hypovolemic. Bleeding from a Meckel diverticulum can also be less dramatic, with melanotic stools.

Less often, a Meckel diverticulum may be associated with partial or complete bowel obstruction. The most common mechanism of obstruction occurs when the diverticulum acts as the lead point of an intussusception. This presentation is more common in older male children. Other causes of obstruction may result from intraperitoneal bands connecting residual omphalomesenteric duct remnants to the ileum and umbilicus. These bands cause obstruction by internal herniation or volvulus of the small bowel around the band. A Meckel diverticulum may occasionally become inflamed (diverticulitis) and present similarly to acute appendicitis. Diverticulitis may lead to perforation and peritonitis.

Figure 312.2-1 Typical Meckel diverticulum located on the antimesenteric border.

Figure 312.2-2 Meckel scan demonstrating accumulation of technetium in the stomach superior bladder (inferior) and in the acid-secreting mucosa of a Meckel diverticulum.

Diagnosis.

The diagnosis of omphalomesenteric duct remnants depends on their clinical presentation. If an infant or child presents with significant painless rectal bleeding, the presence of a Meckel diverticulum should be suspected. Confirmation of a Meckel diverticulum can be difficult. Plain abdominal radiographs are of no value, and routine barium studies rarely fill the diverticulum. The most sensitive study is a Meckel radionuclide scan, which is performed after intravenous infusion of technetium-99m pertechnetate. The mucus-secreting cells of the ectopic gastric mucosa take up pertechnetate, permitting visualization of the Meckel diverticulum (Fig. 312–2). The uptake can be enhanced with various agents, including cimetidine, glucagon, and gastrin. The sensitivity of the enhanced scan is approximately 85%, with a specificity of approximately 95%. Other methods of detection include abdominal ultrasound, superior mesenteric angiography, abdominal CT scan, and exploratory laparoscopy. In patients who present with intestinal obstruction or a picture of appendicitis with omphalomesenteric duct remnants, the diagnosis is rarely made before surgery. The treatment of a symptomatic Meckel diverticulum is surgical excision.

Chapter 313 - Motility Disorders and Hirschsprung Disease

Robert Wyllie

313.1 Chronic Intestinal Pseudo-Obstruction

Chronic intestinal pseudo-obstruction comprises a group of disorders characterized by signs and symptoms of intestinal obstruction in the absence of an anatomic lesion. Pseudo-obstruction may occur as a primary disease or may be secondary to a large number of conditions that may transiently or permanently alter bowel motility. Pseudo-obstruction represents a wide spectrum of pathologic disorders from abnormal myoelectric activity to abnormalities of the nerves (intestinal neuropathy) or musculature (intestinal myopathy) of the gut. The organs involved may include the entire gastrointestinal tract or may be limited to certain components, such as the stomach or colon. The distinctive pathologic abnormalities are considered together because of their clinical similarities.

Most congenital forms of pseudo-obstruction occur sporadically. A few clusters of autosomal dominant or recessive individuals have been reported as having cases associated with abnormal gut muscle or nerves. Patients with autosomal dominant forms of pseudo-obstruction have variable expressions of the disease. Acquired pseudo-obstruction may follow episodes

of acute gastroenteritis, presumably resulting in injury to the myenteric plexus.

In congenital pseudo-obstruction, abnormalities of the muscle or nerves can be demonstrated in most cases. In muscular disease, the outer longitudinal muscle layer is replaced by fibrous material. In neuronal disease, there may be disorganized or hypoganglionosis or hyperganglionosis. Abnormalities in the interstitial cells of Cajal have been demonstrated in some children and mitochondrial defects found in others.

Clinical Manifestations.

More than half the children with congenital pseudo-obstruction experience symptoms within the first few months of life. Two thirds of the infants presenting within the first few days of life are born prematurely, and about 40% have malrotation of the intestine. In 75% of these children symptoms occur during the 1st yr of life, and the remainder become symptomatic in the next several years. The most common symptoms are abdominal distention and vomiting, which are present in 75% of affected infants. Constipation, growth failure, and abdominal pain occur in approximately 60% of patients, and diarrhea occurs in 30–40%. The symptoms wax and wane in the majority of the patients; poor nutrition and intercurrent illness tend to exacerbate symptoms. Urinary tract involvement is not uncommon and may present as recurrent urinary tract infection or mimic obstructive symptoms.

The diagnosis of pseudo-obstruction is based on the presence of compatible symptoms in the absence of anatomic obstruction. Plain abdominal radiographs demonstrate air-fluid levels in the small intestine. Neonates with evidence of obstruction at birth have a microcolon. Contrast studies demonstrate slow passage of barium; consideration should be given to using water-soluble agents.

Other studies may provide information on the underlying pathophysiology. Esophageal motility is abnormal in about half the patients. Antroduodenal motility and gastric emptying studies have abnormal results if the upper gut is involved. Manometric evidence of a normal migrating motor complex should redirect the diagnostic evaluation. Anorectal motility is normal and differentiates pseudo-obstruction from Hirschsprung disease. Full-thickness intestinal biopsy may show involvement of the muscle layers or abnormalities of the intrinsic intestinal nervous system.

The *differential diagnosis* includes Hirschsprung disease, other causes of mechanical obstruction, psychogenic constipation, neurogenic bladder, and superior mesenteric artery syndrome. Secondary causes of ileus or pseudo-obstruction, such as hypothyroidism, narcotics, scleroderma, Chagas disease, hypokalemia, diabetic neuropathy, amyloidosis, porphyria, angioneurotic edema, and radiation must be excluded.

Treatment.

Nutritional support is the mainstay of treatment for pseudo-obstruction. Thirty to 50% require partial or complete parenteral nutrition. Some patients can be treated with intermittent enteral supplementation, whereas others may maintain themselves on selective oral diets. Prokinetic drugs are generally not useful. Isolated gastroparesis may follow episodes of viral gastroenteritis and spontaneously resolves usually within 6–24 mo. Cisapride (a 5-hydroxytryptamine receptor antagonist) and erythromycin (a motilin receptor agonist) may enhance gastric emptying and proximal small bowel motility and may be of use in this selected group of patients.

Symptomatic small bowel bacterial overgrowth is usually treated with oral antibiotics. Bacterial overgrowth may be associated with steatorrhea and malabsorption. Antibiotics should be used judiciously, however, because they may lead to the emergence of drug-resistant bacteria. Patients with acid peptic symptoms are treated with acid suppressors (see Chapter 316). Some children benefit from decompressive ileostomies or colostomies. Colectomy with ileorectal anastomosis is beneficial if the large bowel is the primary site of the motility abnormality. Bowel transplantation may benefit selected patients.

313.2 Functional Constipation

Constipation is defined by a delay or difficulty in defecation that has been present for 2 wk or longer. Functional constipation, also known as idiopathic constipation or fecal withholding, can usually be differentiated from constipation secondary to organic causes on the basis of a history and physical examination. Unlike anorectal malformations and Hirschsprung disease, functional constipation typically starts after the neonatal period. The constipation is caused by the passage of painful bowel movements with voluntary withholding of feces to avoid the painful stimulus. Perianal inflammation from milk protein allergy may initiate the painful stimuli. When children have the urge to defecate, typical behaviors include contracting the gluteal muscles by stiffening the legs while lying down or holding onto furniture while standing. Some children will squat or hide while passing stool. Caregivers may misinterpret these activities as straining. Daytime encopresis is common, and some children will have a history of blood in the stool noted with the passage of a large bowel movement. Findings suggestive of underlying pathology include failure to thrive, weight loss, abdominal pain, vomiting, or persistent anal fissure or fistula.

The physical examination often demonstrates a large volume of stool palpated in the suprapubic area; rectal examination demonstrates a dilated rectal vault filled with guaiac-negative stool. The presence of a hair tuft over the spine, spinal dimple, or failure to elicit a cremasteric reflex or anal wink is suggestive of spinal pathology. A tethered cord is suggested by decreased or absent lower leg reflexes. Urinary tract symptoms include recurrent urinary tract infection; evidence of obstruction may occur in constipated children and those with spinal disorders. Children with no evidence of abnormalities on physical examination rarely require radiologic evaluation. In refractory patients, specialized testing should be considered to rule out conditions such as hypothyroidism, hypocalcemia, lead toxicity, and celiac disease. Selected

children may benefit from MRI of the spine to identify an intraspinal process, motility studies to identify underlying myopathy or neuropathic bowel abnormalities, or a barium enema to identify structural abnormalities.

Therapy for functional constipation includes patient education, relief of impaction, and softening of the stool. The parents must understand that soiling associated with overflow incontinence is associated with loss of normal sensation and not a willful act. A regular bowel training program including sitting on the toilet for 5–10?min after meals and keeping track of the frequency of bowel movements is often helpful in establishing a regular bowel habit. If an impaction is present on the initial physical examination, an enema is usually required to clear the impaction while bowel softeners are started as maintenance medications. Typical regimens include the use of mineral oil, lactulose, and polyethylene glycol preparation. Prolonged use of stimulants such as senna or bisacodyl should be avoided. Children with behavioral problems that are interfering with successful treatment may benefit from a referral to a mental heath care provider. Maintenance therapy is generally continued until a regular bowel pattern has been established for several months. Children with spinal problems can be successfully managed with low volumes of fluid through a cecostomy tube.

313.3 Congenital Aganglionic Megacolon (Hirschsprung Disease)

Hirschsprung disease, or congenital aganglionic megacolon, is caused by abnormal innervation of the bowel, beginning in the internal anal sphincter and extending proximally to involve a variable length of gut. Hirschsprung disease is the most common cause of lower intestinal obstruction in neonates, with an overall incidence of 1 in 5,000 live births. Males are affected more often than females (4:1); prematurity is uncommon. There is an increased familial incidence in long segment disease. Hirschsprung disease may be associated with other congenital defects, including Down, Smith-Lemli-Opitz, Waardenburg, cartilage-hair hypoplasia, and congenital hypoventilation (“Ondine curse”) syndromes and urogenital or cardiovascular abnormalities.

Pathology.

Hirschsprung disease is result of an absence of ganglion cells in the bowel wall, extending proximally and continuously from the anus for a variable distance. The absence of neural innervation is a consequence of an arrest of neuroblast migration from the proximal to distal bowel. Hirschsprung disease is usually sporadic; however, dominant and recessive patterns of inheritance have been demonstrated in family groups. Genetic defects have been identified most often on the *RET* gene localized on chromosome 10q11 and the *EDNRB* gene located on 13q22. Defects in *SOX10* (22q13) have been associated with Hirschsprung disease and Waardenburg syndrome. Other mutations that have been identified include gene defects in *GDNF* and *NTN,* which are involved in *RET* activation, and defects in *EDN3* and *ECE1,* which are involved in *EDNRB* initiation. The aganglionic segment is limited to the rectosigmoid in 75% of patients; in 10% the entire colon lacks ganglion cells. Total bowel aganglionosis is rare. Observed histologically is an absence of Meissner and Auerbach plexus and hypertrophied nerve bundles with high concentrations of acetylcholinesterase between the muscular layers and in the submucosa.

Clinical Manifestations.

The clinical symptoms of Hirschsprung disease usually begin at birth with the delayed passage of meconium. In 99% of full-term infants, meconium is passed within 48?hr of birth. Hirschsprung disease should be suspected in any full-term infant (the disease is unusual in preterm infants) with delayed passage of stool. Some infants pass meconium normally but subsequently present with a history of chronic constipation. Failure to thrive, with hypoproteinemia from a protein-losing enteropathy, is a less common presentation now that Hirschsprung disease is usually recognized early in the course of the illness. Breast-fed infants may not suffer as severe a disease as formula-fed infants.

Failure to pass stool leads to dilatation of the proximal bowel and abdominal distention. As the bowel dilates, intraluminal pressure increases, resulting in decreased blood flow and deterioration of the mucosal barrier. Stasis allows proliferation of bacteria, which may lead to enterocolitis (*Clostridium difficile, Staphylococcus aureus,* anaerobes, coliforms) with associated sepsis and signs of bowel obstruction. Early recognition of Hirschsprung disease before the onset of

enterocolitis is essential in reducing morbidity and mortality.

Hirschsprung disease in older patients must be distinguished from other causes of abdominal distention and chronic constipation (Table 313–1 ; Fig. 313–1). The history often reveals increasing difficulty with the passage of stools, starting in the 1st few weeks of life. A large fecal mass is palpable in the left lower abdomen, but on rectal examination the rectum is usually empty of feces. The stools, when passed, may consist of small pellets, may be ribbon-like, or may have a fluid consistency; the large stools and fecal soiling of patients with functional constipation are absent. In neonates, Hirschsprung disease must be differentiated from meconium plug syndrome, meconium ileus, and intestinal atresia. In older patients, the Currarino triad must be considered (anorectal malformations—ectopic, anus, rectal stenosis; sacral bone anomalies—hypoplasia, poor segmentation; or presacral masses—anterior meningoceles, teratoma, cysts).

Rectal examination demonstrates normal anal tone and is usually followed by an explosive discharge of foul-smelling feces and gas. Intermittent attacks of intestinal obstruction from retained feces may be associated with pain and fever.

Diagnosis.

Rectal manometry and rectal suction biopsy are the easiest and most reliable indicators of Hirschsprung disease. Anorectal manometry measures the pressure of the internal anal sphincter while a balloon is distended in the rectum. In normal individuals, rectal distention initiates a reflex decline in internal sphincter pressure. In patients with Hirschsprung disease, the pressure fails to drop or there is a paradoxical rise in pressure with rectal distention. The accuracy of this diagnostic test is more than 90%, but it is technically difficult in young infants. A normal response in the course of manometric evaluation precludes a diagnosis of Hirschsprung disease; an equivocal or paradoxical response requires a rectal biopsy.

TABLE 313.3-1 -- **Distinguishing Features of Hirschsprung Disease and Functional Constipation**

Variable	Functional (Acquired)	Hirschsprung Disease
History		
Onset of constipation	After 2 yr of age	At birth
Encopresis	Common	Very rare
Failure to thrive	Uncommon	Possible
Enterocolitis	None	Possible
Forced bowel training	Usual	None
Examination		
Abdominal distention	Uncommon	Common
Poor weight gain	Rare	Common
Anal tone	Normal	Normal
Rectal examination	Stool in ampulla	Ampulla empty
Malnutrition	None	Possible
Laboratory		
Anorectal manometry	Distention of the rectum causes relaxation of the internal sphincter	No sphincter relaxation or paradoxical increase in pressure
Rectal biopsy	Normal	No ganglion cells Increased acetylcholinesterase staining
Barium enema	Massive amounts of stool, no transition zone	Transition zone, delayed evacuation (>24 hr)

Figure 313.3-1 Barium enema in a 14-yr-old boy with severe constipation. The enormous dilatation of the rectum and distal colon is typical of acquired functional megacolon.

Rectal suction biopsies should be performed no closer than 2?cm to the dentate line to avoid the normal area of hypoganglionosis at the anal verge. The biopsy material should contain an adequate sample of submucosa to evaluate for the presence of ganglion cells. The biopsy specimen can be stained for acetylcholinesterase, which may facilitate interpretation. Patients with aganglionosis demonstrate a large number of hypertrophied nerve bundles that stain positively for acetylcholinesterase with an absence of ganglion cells.

The radiographic diagnosis of Hirschsprung disease is based on the presence of a transition zone between normal dilated proximal colon and a smaller-caliber obstructed distal colon caused by the nonrelaxation of the aganglionic bowel. The transition zone is not usually present before 1–2 wk of age and on a radiograph is a funnel-shaped area of intestine between the proximal dilated colon and the

constricted distal bowel. Radiologic evaluation should be performed without preparation to prevent transient dilatation of the aganglionic segment. Twenty-four-hour delayed films are helpful (Fig. 313–2). If significant barium is still present in the colon, it increases the suspicion of Hirschsprung disease even if a transition zone is not identified. Barium enema examination is useful in determining the extent of aganglionosis before surgery and in evaluating other diseases that present as lower bowel obstruction in a neonate. Full-thickness rectal biopsy may be performed at the time of surgery to confirm the diagnosis and level of involvement.

Treatment.

Once the diagnosis is established, the definitive treatment is operative intervention. The operative options

Figure 313.3-2 Lateral view of a barium enema in a 3-yr-old girl with Hirschsprung disease. The aganglionic distal segment is narrow, with distended normal ganglionic bowel above it.

are to perform a definitive procedure as soon as the diagnosis is established or perform a temporary colostomy and wait until the infant is 6–12 mo old to perform definitive repair. There are three basic surgical options. The first successful surgical procedure, described by Swenson, was to excise the aganglionic segment and anastomose the normal proximal bowel to the rectum 1–2?cm above the dentate line. The operation is technically difficult and led to the development of two other procedures. Duhamel described a procedure to create a neorectum, bringing down normally innervated bowel behind the aganglionic rectum. The neorectum created in this procedure has an anterior aganglionic half with normal sensation and a posterior ganglionic half with normal propulsion. The endorectal pull-through procedure described by Boley involves stripping the mucosa from the aganglionic rectum and bringing normally innervated colon through the residual muscular cuff, thus bypassing the abnormal bowel from within. Advances in techniques have led to successful laparoscopic pull-through.

In ultrashort segmental Hirschsprung disease or internal sphincter achalasia, the aganglionic segment is limited to the internal sphincter. The clinical symptoms are similar to those of children with functional constipation. Ganglion cells are present on rectal suction biopsy, but the rectal motility is abnormal. Excision of a strip of rectal muscle usually leads to a more regular bowel pattern.

Long-segment Hirschsprung disease involving the entire colon and part of the small bowel represents a difficult problem. Rectal motility studies and rectal suction biopsy demonstrate findings of Hirschsprung disease, but radiologic studies are difficult

to interpret because no colonic transition zone can be identified. The extent of aganglionosis can be determined accurately by biopsy at the time of laparotomy. When the entire colon is aganglionic, often together with a length of terminal ileum, ileal-anal anastomosis is the treatment of choice, preserving part of the aganglionic colon to facilitate water absorption, which helps the stools to become firm.

The prognosis of surgically treated Hirschsprung disease is generally satisfactory; the great majority of patients achieve fecal continence. Postoperative problems include recurrent enterocolitis, stricture, prolapse, perianal abscesses, and fecal soiling.

313.4 Superior Mesenteric Artery Syndrome (Wilkie Syndrome, Cast Syndrome, Arteriomesenteric Duodenal Compression Syndrome)

The superior mesenteric artery syndrome describes an extrinsic compression of the duodenum in children after rapid weight loss and in a supine position. The compression is thought to occur as the mesentery loses its fat and allows the superior mesenteric artery to collapse on the duodenum, compressing it between the superior mesenteric artery anteriorly and the aorta posteriorly. Alternatively, the cause may be that the loss of supporting fat in the second and third portions of the duodenum allows the duodenum to collapse against the spine.

The classic example is an adolescent who starts vomiting after application of a body cast for orthopedic surgery. Other associated factors include anorexia, prolonged bed rest, weight loss, abdominal surgery, and exaggerated lumbar lordosis. The *diagnosis* is established radiologically with the demonstration of a cutoff of the duodenum just to the right of the midline. The duodenal obstruction may be

accompanied by proximal duodenal and gastric dilatation.

Treatment of the acute syndrome involves relief of the obstruction and improved nutrition to alter the anatomic relationships of the duodenum with surrounding structures. Positioning patients in a lateral or prone position shifts the duodenum away from potential obstructing structures and may allow resumption of oral intake. Prokinetic agents such as metoclopramide or cisapride may be helpful. If repositioning is unsuccessful in relieving symptoms, a nasojejunal tube may be placed past the point of obstruction and feedings begun. Some patients require total parenteral nutrition to replete lost body fat, and occasional patients may need surgical intervention.

Chapter 314 - Ileus, Adhesions, Intussusception, and Closed-Loop Obstructions

Robert Wyllie

314.1 Ileus

Ileus is the failure of intestinal peristalsis without evidence of mechanical obstruction. Lack of normal gut motility interferes with aboral movement of intestinal contents and in children is most often associated with abdominal surgery or infection (pneumonia, gastroenteritis, peritonitis). Ileus also accompanies metabolic abnormalities, such as uremia, hypokalemia, or acidosis, and occurs with administration of certain drugs, such as opiates and vincristine. Ileus may also occur when antimotility drugs such as loperamide are used during episodes of gastroenteritis.

Ileus presents as increasing abdominal distention and initially minimal pain. Pain increases with increasing distention. Bowel sounds are minimal or absent, in contrast to early mechanical obstruction, when they are hyperactive. Plain abdominal radiographs demonstrate many air-fluid levels throughout the abdomen. Serial radiographs usually do not show progressive distention as they do in mechanical obstruction. Contrast radiographs, if performed, demonstrate slow movement of the barium through a patent lumen.

Treatment of ileus involves correction of the underlying abnormality. Nasogastric decompression is used if abdominal distention is associated with pain or to relieve recurrent vomiting. Ileus after abdominal surgical procedures usually results in return of normal intestinal motility within 24–72?hr. Prokinetic agents such as metoclopramide or erythromycin may stimulate the return of normal bowel motility and be of assistance to children with prolonged ileus. Oral administration of drugs that block gastrointestinal opiate receptors but do not block central nervous system opiate action may reduce the ileus in postoperative patients receiving narcotics.

314.2 Adhesions

Adhesions are fibrous bands of tissue that are a common cause of postoperative small bowel obstruction after abdominal surgery. The risk of forming an adhesion that causes obstructive symptoms in childhood has not been well studied but seems to occur in 2–3% of patients after abdominal surgery. The majority of obstructions

are associated with single adhesions and can occur at any time after the 2nd postoperative week.

The *diagnosis* is suspected in patients with abdominal pain, constipation, emesis, and a history of intraperitoneal surgery. Nausea and vomiting quickly follow the development of pain. Bowel sounds initially are hyperactive, and the abdomen is flat. The bowel subsequently dilates, producing abdominal distention in most patients, and bowel sounds disappear. Fever and leukocytosis are suggestive of necrotic bowel and peritonitis. Plain radiographs demonstrate obstructive features, and contrast studies may be needed to define the cause of obstruction.

Patients with suspected obstruction should have nasogastric decompression, intravenous fluid resuscitation, and broad-spectrum antibiotics in anticipation of surgery. Nonoperative intervention is contraindicated unless a patient is stable with clear evidence of clinical improvement.

314.3 Intussusception

Intussusception occurs when a portion of the alimentary tract is telescoped into an adjacent segment. It is the most common cause of intestinal obstruction between 3 mo and 6 yr of age. Sixty per cent of patients are younger than 1 yr, and 80% of the cases occur before 24 mo; it is rare in neonates. The incidence varies from 1–4 in 1,000 live births. The male:female ratio is 4:1. A few intussusceptions reduce spontaneously, but if left untreated, most will lead to peritonitis, perforation, and death.

Etiology and Epidemiology.

The cause of most intussusceptions is unknown. The seasonal incidence has peaks in spring and autumn. Correlation with adenovirus infections has been noted, and the condition may complicate otitis media, gastroenteritis, Henoch-Schönlein purpura, or upper respiratory tract infections. The risk of intussusception in infants 1 yr of age or younger after receiving the tetravalent rhesus-human reassortant rotavirus vaccine within 2 wk of immunization is substantially increased (odds ratio: 21:7). The risk is much greater after the first dose of the vaccine compared with the risk after the second dose. The Advisory Committee on Immunization Practices no longer recommends this vaccine. Although wild-type human rotavirus produces an enterotoxin, it is rarely detected in cases of spontaneous intussusception.

It is postulated that gastrointestinal infection or the introduction of new food proteins results in swollen Peyer patches in the terminal ileum. The prominent mounds of tissue lead to mucosal prolapse of the ileum into the colon, thus causing an intussusception. In 2–8% of patients, recognizable lead points for the intussusception are found, such as a Meckel diverticulum, intestinal polyp, neurofibroma, intestinal duplication, hemangioma, or malignant conditions such as lymphoma. Intussusception may complicate mucosal hemorrhage as in Henoch-Schönlein purpura or hemophilia. Cystic fibrosis is another risk factor. Postoperative intussusception is ileoileal and usually occurs within 5 days of an abdominal operation. Lead points are more common in children older than 2 yr of age. Intrauterine intussusception is associated with the development of intestinal atresia.

Pathology.

Intussusceptions are most often ileocolic and ileoileocolic, less commonly cecocolic, and rarely exclusively ileal. Very rarely, the appendix forms the apex of an intussusception. The upper portion of bowel, the intussusceptum, invaginates into the lower, the intussuscipiens, dragging its mesentery along with it into the enveloping loop. Constriction of the mesentery obstructs venous return; engorgement of the intussusceptum follows, with edema, and bleeding from the mucosa leads to a bloody stool, sometimes containing mucus. The apex of the intussusception may extend into the transverse, descending, or sigmoid colon, even to and through the anus in neglected cases. This presentation must be distinguished from rectal prolapse. Most intussusceptions do not strangulate the bowel within the first 24?hr but may later eventuate in intestinal gangrene and shock.

Clinical Manifestations.

In typical cases there is sudden onset, in a previously well child, of severe paroxysmal colicky pain that recurs at frequent intervals and is accompanied by straining efforts with legs and knees flexed and loud cries. The infant may initially be comfortable and play normally between the paroxysms of pain; but if the intussusception is not reduced, the infant becomes progressively weaker and lethargic. At times, the lethargy is out of proportion to the abdominal signs. Eventually a shocklike state may develop with fever. The pulse becomes weak and thready, the respirations become shallow and grunting, and the pain may be manifested only by moaning sounds. Vomiting occurs in most cases and is usually more frequent early. In the later phase, the vomitus becomes bile stained. Stools of normal appearance may be evacuated during the first few hours of symptoms. After this time, fecal excretions are small or more often do not occur and little or no flatus is passed. Blood generally is passed in the first 12?hr but at times not for 1–2 days and infrequently not at all; 60% of infants pass a stool containing red blood and mucus, the *currant jelly stool.* Some patients have only irritability and alternating or progressive lethargy.

Palpation of the abdomen usually reveals a slightly tender sausage-shaped mass, sometimes ill defined, which may increase in size and firmness during a paroxysm of pain and is most often in the right upper abdomen, with its long axis cephalocaudal. If it is felt in the epigastrium, the long axis is transverse. About 30% of patients do not have a palpable mass. The presence of bloody mucus on the finger as it is withdrawn after rectal examination supports the diagnosis of intussusception. Abdominal distention and tenderness develop as intestinal obstruction becomes more acute. On rare occasions, the advancing intestine prolapses through the anus. This prolapse can be distinguished from prolapse of the rectum by the separation between the protruding intestine and the rectal wall, which does not exist in prolapse of the rectum.

Ileoileal intussusception may have a less typical clinical picture, the symptoms and signs being chiefly those of small intestinal obstruction. *Recurrent intussusception* is

noted in 5–8% and is more common after hydrostatic than surgical reduction. *Chronic intussusception,* in which the symptoms exist in milder form at recurrent intervals, is more likely to occur with or after acute enteritis and may arise in older children as well as in infants.

Diagnosis.

The clinical history and physical findings are usually sufficiently typical for diagnosis. Plain abdominal radiographs may show a density in the area of the intussusception. A barium enema shows a filling defect or cupping in the head of barium where its advance is obstructed by the intussusceptum (Fig. 314–1). A central linear column of barium may be visible in the compressed lumen of the intussusceptum, and a thin rim of barium may be seen trapped around the invaginating intestine in the folds of mucosa within the intussuscipiens (coiled-spring sign), especially after evacuation. Retrogression of the intussusceptum under the pressure of the enema and gaseous distention of the small intestine from obstruction are also useful radiographic signs. Ileoileal intussusception is usually not demonstrable by barium enema but is suspected because of gaseous distention of the intestine above the lesion. The use of "air" enemas in the diagnosis and treatment of intussusception has supplanted hydrostatic reduction. Reflux of air into the terminal ileum and the disappearance of the mass at the ileocecal valve document successful reduction. Air reduction is associated with fewer complications and lower radiation exposure than traditional hydrostatic techniques.

Ultrasonography is a sensitive diagnostic tool in the diagnosis of intussusception. The diagnostic findings of intussusception include a tubular mass in longitudinal views and a doughnut or target appearance in transverse images (Fig. 314–2). Ultrasonography is also useful in demonstrating reduction of the intussusception by hydrostatic or air techniques.

DIFFERENTIAL DIAGNOSIS.

It may be particularly difficult to diagnose intussusception in a child who already has *gastroenteritis;* a change in the pattern of illness, in the character of pain, or in the nature of vomiting or the onset of rectal bleeding should alert the physician. The bloody stools and abdominal cramps that accompany *enterocolitis* can usually be differentiated from intussusception because the pain is less severe and less

Figure 314.3-1 Intussusception in an infant. The obstruction is evident in the proximal transverse colon. Contrast material between the intussusceptum and the intussuscipiens is responsible for the coil-spring appearance.

regular, there is diarrhea, and the infant is recognizably ill between pains. Bleeding from *Meckel diverticulum* is usually painless. Joint symptoms or purpura usually but not invariably accompanies the intestinal hemorrhage of Henoch-Schönlein purpura. Because intussusception may be a complication of this disorder, ultrasonography may be needed to distinguish the conditions.

Treatment.

Reduction of an acute intussusception is an emergency procedure and performed immediately after diagnosis in preparation for possible surgery. In patients with prolonged

Figure 314.3-2 Transverse image of an ileocolic intussusception. Note the loops within the loops of bowel.

intussusception with signs of shock, peritoneal irritation, intestinal perforation, or pneumatosis intestinalis, reduction should not be attempted.

The success rate of radiologic reduction under fluoroscopic or ultrasonic guidance is approximately 50% if symptoms are present longer than 48?hr and 70–90% if reduction is done within the first 48?hr. Bowel perforations occur in 0.5–2.5% of attempted barium and hydrostatic (saline) reductions. The perforation rate with air reduction ranges from 0.1–0.2%.

An ileoileal intussusception is best demonstrated by abdominal ultrasonography. Reduction by instillation of barium, saline, or air may not be possible. Such intussusceptions may develop insidiously after bowel surgery and require reoperation if they do not spontaneously reduce. If manual operative reduction is impossible or the bowel is not viable, resection of the intussusception is necessary, with end-to-end anastomosis.

Prognosis.

Untreated intussusception in infants is almost always fatal; the chances of recovery are directly related to the duration of intussusception before reduction. Most infants recover if the intussusception is reduced within the first 24?hr, but the mortality rate rises rapidly after this time, especially after the 2nd day. Spontaneous reduction during preparation for operation is not uncommon.

The recurrence rate after barium enema reduction of intussusceptions is about 10%, and after surgical reduction it is 2–5%; none has recurred after surgical resection. The administration of dexamethasone has been reported to reduce the frequency of recurrent intussusception. Recurrent intussusception can usually be reduced radiologically. It is unlikely that an intussusception caused by a lesion such as lymphosarcoma, polyp, or Meckel diverticulum will be successfully reduced by radiologic intervention. With adequate surgical management, operative reduction carries a very low mortality rate in early cases.

314.4 Closed-Loop Obstructions

Intestinal obstruction may be caused by defects in the mesentery ("internal hernias") through which loops of small bowel may pass and become trapped. Vascular engorgement of the trapped bowel results in intestinal ischemia and gangrene unless promptly relieved. Symptoms include bilious vomiting, abdominal distention, and

abdominal pain. Peritoneal signs suggest ischemic bowel. Plain radiographs demonstrate signs of small bowel obstruction or free air if the bowel has perforated. Supportive management includes intravenous fluids, antibiotics, and nasogastric decompression. Prompt surgical relief of the obstruction is indicated if intestinal gangrene is to be prevented. Symptoms can occasionally be transient or recurrent if the herniated bowel slides out of the mesenteric defect, spontaneously relieving the obstruction.

Chapter 315 - Foreign Bodies and Bezoars

Robert Wyllie

315.1 Foreign Bodies in the Stomach and Intestine

Eighty percent of all foreign body ingestions occur in children, with a peak incidence between the ages of 6 mo and 3 yr. Coins are the most common foreign body ingested by young children. In older children, teenagers, and adults, fish or chicken bones are the most common objects accidentally ingested. The risk of ingestion increases after alcohol consumption or cold liquids because of a decrease in oral sensory acuity. Repeat ingestion may occur in young children and psychiatrically impaired patients. Of the foreign bodies that come to medical attention, 80–90% pass through the gastrointestinal tract without difficulty. Ten to 20% require endoscopic removal or other conservative management, whereas 1% or less require surgical intervention. Once in the stomach, 95% of all ingested objects pass without difficulty through the remainder of the gastrointestinal tract. Perforation after ingestion of a foreign body is estimated to be less than 1% of all objects ingested. Perforation tends to occur in areas of physiologic sphincters (pylorus and ileocecal valve), acute angulation (such as the duodenal sweep), congenital gut malformations (webs, diaphragms, or diverticula), or areas of previous bowel surgery.

Patients with nonfood foreign bodies often describe a history of ingestion. Young children may have a witness to ingestion. Approximately 90% of foreign bodies are opaque. Radiologic examination is routinely performed to determine the type, number, and location of the suspected objects. Contrast radiographs may be necessary to demonstrate some objects such as plastic parts or toys.

Conservative management is indicated in most foreign bodies that have passed through the esophagus and entered the stomach. Most objects pass though the intestine in 4–6 days, although some may take as long as 3–4 wk. While waiting for the object to pass, parents are instructed to continue a regular diet and to observe the stools for the appearance of the ingested object. Cathartics should be avoided. Exceptionally long or sharp objects are usually monitored radiologically. Parents or patients should be instructed to report abdominal pain, vomiting, persistent fever, and hematemesis or melena immediately to their physician. Failure of the object to progress over a 3- to 4-wk period seldom implies an impeding perforation but may be

associated with a congenital malformation or acquired bowel abnormality.

In older children and adults, oval objects greater than 5?cm in diameter or 2?cm in thickness tend to lodge in the stomach and should be endoscopically retrieved. Thin objects greater than 10?cm in length fail to negotiate the duodenal sweep and should also be removed. In infants and toddlers, objects longer than 3?cm or larger than 20?mm in diameter usually do not pass through the pylorus and should be removed. Open safety pins should also be endoscopically retrieved, but other sharp objects can be managed conservatively. Drugs (aggregated iron pills, cocaine packing) may need to be surgically removed; initial management may include oral polyethylene glycol lavage.

Children occasionally place objects in their rectum. Small, blunt objects usually pass spontaneously, but large or sharp objects usually need to be retrieved. Adequate sedation is essential to relax the anal sphincter before attempted endoscopic or speculum removal. If the object is proximal to the rectum, observation for 12–24?hr usually allows the object to descend into the rectum.

315.2 Bezoars

A bezoar is an accumulation of exogenous matter in the stomach or intestine. Most bezoars have been found in females with underlying personality problems or in neurologically impaired individuals. Patients who have undergone abdominal surgery are at higher risk for the development of bezoars. The peak age at onset of symptoms is the second decade of life. Bezoars are classified on the basis of their composition. Trichobezoars are composed of the patient's own hair, and phytobezoars are composed of a combination of plant and animal material. Lactobezoars were previously found most often in premature infants and may be attributed to the high casein or calcium content of some premature formulas. Swallowed chewing gum may occasionally lead to a bezoar.

Trichobezoars can become large and form casts of the stomach; they may enter into the proximal duodenum. They present as symptoms of gastric outlet or partial intestinal obstruction including vomiting, anorexia, and weight loss. Patients may complain of abdominal pain, distention, and severe halitosis. Physical examination may demonstrate patchy baldness and a firm mass in the left upper quadrant. Patients may occasionally have iron-deficiency anemia, hypoproteinemia, or steatorrhea caused by an associated chronic gastritis. Phytobezoars present in a similar manner.

An abdominal plain film may suggest the presence of a bezoar, which can be confirmed on ultrasound or CT examination. Bezoars in the stomach can usually be removed endoscopically. If endoscopy is unsuccessful, surgical intervention may be needed. Lactobezoars usually resolve when feedings are withheld for 24–48?hr.

Chapter 316 - Peptic Ulcer Disease

Francisco A. Sylvester

Ulcers are deep lesions that breech the integrity of the epithelium and penetrate through the muscularis mucosae, whereas erosions are superficial and stop short of the muscularis propria. Both lesions often occur in the presence of gastric inflammation or *gastritis*.

Gastric and duodenal ulcers occur infrequently in children; the precise prevalence is unknown. Gastritis and ulcers of the duodenum or stomach can be classified either as primary or secondary. This classification is arbitrary and predates the knowledge of the association between *Helicobacter pylori* infection and duodenal and gastric ulcers.

The majority of children with active gastritis and ulcers in the stomach or duodenum will have an associated systemic

condition, such as overwhelming sepsis, severe head or body trauma, or burns, or be on medications such as nonsteroidal anti-inflammatory drugs. Other conditions associated with upper gastrointestinal inflammation include inflammatory bowel disease (particularly Crohn disease), eosinophilic gastroenteritis, allergic enteropathy, hypertrophic gastritis (Ménétrier disease), autoimmune gastritis, varioliform (lymphocytic) gastritis, and Zollinger-Ellison syndrome. In addition, although uncommon, secondary ulcers have been reported as sequelae to hepatic disease, cystic fibrosis, and sickle cell anemia.

Children who do not have any obvious systemic disease who present with gastritis and/or ulcers are said to have “primary” gastroduodenal inflammation. In most of these patients, the inflammation is caused by *Helicobacter pylori*. *H. pylori* is a gram-negative spiral organism with polar flagellae that lives primarily in the mucus layer covering gastric epithelial cells. A portion of the bacterial population attaches to gastric epithelial cells via specific adhesins. To survive in the harsh environment of the acidic stomach, *H. pylori* produces urease, an enzyme that catalyzes the conversion of urea in the gastric juice to ammonia and bicarbonate. These products buffer the gastric acid and create a friendly microenvironment for *H. pylori*. This property is the basis for several diagnostic tests, such as rapid urease tests and the urea breath test (see later). Humans appear to be the primary natural reservoir of *H. pylori* infection. There is no known animal or insect reservoir of *H. pylori*. *Helicobacter* species are present in many animals. Humans occasionally can become infected with *Helicobacter* species harbored in domestic animals (e.g., *H. heilmanii*).

In most individuals, *H. pylori* is acquired early in life (before 5?yr). Although the precise mechanism of transmission is not yet known, person-to-person contagion in close contacts and family members is strongly suspected. The route of transmission may involve fecal-oral, gastric-oral (in vomitus), or oral-oral routes. Crowding and poor sanitary conditions are risk factors for acquisition of *H. pylori*. *H. pylori* infection is more common in Third World countries, where over 90% of adults may be infected. In North America, it is estimated that about one third of the adult population is infected; the prevalence of infection may be decreasing.

Based on epidemiologic and animal studies, colonization with *H. pylori* may predispose to the development of gastric adenocarcinoma and mucosal associated lymphoid tissue (MALT) lymphoma, particularly when the infection is acquired early in life. It is likely that other factors (e.g., high-salt diet, diet with low consumption of fresh fruits and vegetables, and other environmental factors) need to occur concurrently for cancer to evolve. Studies showing that *H. pylori* eradication during childhood prevents subsequent development of gastric malignancies have yet to be performed.

Although colonization with *H. pylori* leads to a vigorous immune response in the stomach, once acquired the infection tends to be permanent, unless it is treated with antibiotics. In the vast majority of individuals, *H. pylori* infection is silent, even in the presence of chronic active gastritis. Serologic surveys, endoscopic evaluations, and treatment trials conducted in adults with dyspepsia (pain or discomfort in the upper abdomen) suggest that in the absence of a peptic ulcer *H. pylori* probably does not cause abdominal pain. Studies in children also have questioned the role of *H. pylori* as a cause of abdominal pain in the absence of peptic ulceration. Guidelines by the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) suggest that the goal of diagnostic testing in children with abdominal pain should be to determine the cause of presenting symptoms rather than the presence of *H. pylori* infection.

Pathogenesis.

The pathogenesis of peptic ulcer disease is incompletely understood. Ulceration occurs when aggressive factors (e.g., gastric acid, digestive enzymes, *H. pylori* bacterial products) overwhelm the natural barriers that protect the gastroduodenal lining (bicarbonate-mucus barrier, gastric epithelial cells, mucosal blood flow, prostaglandins). Patients with duodenal ulceration may have increased acid secretion, whereas patients with gastric ulcers may have reduced acid output. Drugs such as nonsteroidal anti-inflammatory agents inhibit protective prostaglandin synthesis and reduce the mucosal production of bicarbonate. *H. pylori* colonization leads to a blunted response of duodenal bicarbonate secretion in response to intraluminal acidification in adults. Also, the ability of mucins (mucus glycoprotein) to normally polymerize may be altered in patients with duodenal ulcers. Patients who

develop ulcers may be genetically predisposed; increased levels of pepsinogen I are seen in children with duodenal ulcers and their parents. Peptic ulcer disease may be present in either parent of an affected child.

Clinical Manifestations.

The classic symptom of peptic ulceration, epigastric pain alleviated by the ingestion of food, is present only in a minority of children. Most pediatric patients will present with poorly localized abdominal pain, which may be periumbilical. However, the vast majority of patients with periumbilical or epigastric pain or discomfort will not have a peptic ulcer but rather a functional gastrointestinal disorder, such as irritable bowel syndrome or functional dyspepsia, respectively. Patients with peptic ulceration rarely present with acute abdominal pain from perforation or symptoms and signs of pancreatitis from a penetrating ulcer. Patients can also present with gastrointestinal bleeding, with hematemesis and/or melena. Occasionally, bright red blood per rectum may be seen if the rate of bleeding is brisk and the intestinal transit time is short. Vomiting may be a sign of gastric outlet obstruction.

In the 1st mo of life, the two main manifestations are gastrointestinal hemorrhage and perforation. Between the neonatal period and 2 yr of age, recurrent vomiting, slow growth, and gastrointestinal hemorrhage are the major symptoms. In preschool-aged children, periumbilical postprandial pain is often elicited whereas vomiting and hemorrhage remain common. After 6 yr of age, the clinical features of ulcer disease are similar to those in adults and commonly include epigastric abdominal pain, acute or chronic gastrointestinal blood loss (hematemesis, hematochezia, or melena) often leading to iron-deficiency anemia, predominantly male gender, and a strong family history of ulcer disease. The pain is often described as dull or aching rather than sharp or burning, as in adults. It may last from minutes to hours, and patients have frequent exacerbations and remissions lasting from weeks to months. Nocturnal pain is common. A history of typical ulcer pain with prompt relief after taking antacids is found in fewer than 33% of patients. Rarely, in patients with acute or chronic blood loss, penetration of the ulcer into the abdominal cavity or adjacent organs produces shock, anemia, peritonitis, or pancreatitis. If inflammation and edema are extensive, acute or chronic gastric obstruction may occur.

Diagnosis.

Endoscopy is the method of choice to diagnose peptic ulcer disease in children. It provides an opportunity to examine the upper gastrointestinal tract for the presence of inflammation, erosion, and ulceration and to take biopsy samples for microscopic examination and other tests. Endoscopy can also be used therapeutically. Endoscopic accessories can be used to clip, ligate, cauterize, or resect bleeding tissues. An experienced therapeutic endoscopist is required to perform these procedures. The disadvantages of endoscopy include cost and the need for sedation or anesthesia.

Contrast radiography is of limited value in the diagnosis of peptic ulcers in children, with both false-positive and false-negative findings. These studies are helpful, however, in determining the anatomy of the upper gastrointestinal tract.

There are several invasive and noninvasive tests available to detect *H. pylori* infection. Testing for *H. pylori* is recommended only when there is a documented duodenal or gastric ulcer and when there is MALT lymphoma. There are no convincing data to support routine testing of children with recurrent abdominal pain or children who are asymptomatic. The accuracy of a specific diagnostic test is greatly impacted by the prevalence of *H. pylori* in the community. In areas of low prevalence, such as North America, endoscopy is the most reliable test to establish not only the presence of infection but also its consequences in children. Endoscopy frequently shows antral micronodules that represent lymphoid follicles in *H. pylori*–infected children. To confirm the presence of infection, biopsy specimens should be obtained from the antrum, the body, and the transition zones of the stomach. This is especially important in patients who have been on antacid therapy, because *H. pylori* will migrate proximally, away from the antrum in such patients. Tissue samples can then be stained to detect *H. pylori* and to examine the severity and chronicity of the gastritis. Rapid urease tests can be performed in biopsy samples. In this test, biopsy specimens are placed in a well containing agar with a pH-sensitive dye. Presence of urease-producing organisms in the sample is signaled by a color change. Specimens can also be cultured in microaerophilic conditions to establish patterns of antibiotic sensitivity, especially in patients in whom treatment has failed to eradicate the bacteria. *H. pylori* is a fastidious organism, and cultures are best performed by a skilled microbiologist. Noninvasive tests include *H. pylori* antibody detection in serum, whole blood, urine, or saliva and antigen detection in stool. These tests have low sensitivity and specificity in low prevalence areas, especially in children. Treatment based on the results of these tests cannot be recommended. Most of these tests do not distinguish between past and present infection and therefore are not reliable to document eradication. The urea breath test (UBT) is another noninvasive method in which urea labeled with an isotope of carbon (either ^{14}C or ^{13}C) is ingested by the patient. Samples of exhaled air are then collected to detect the presence of labeled carbon dioxide released from the breakdown of urea in the stomach. The UBT is highly sensitive and specific, but the methodology has not yet been standardized for children. This test requires a cooperative child to provide adequate

TABLE 316-1 -- Recommended Eradication Therapies for *H. pylori* Disease in Children

Medications	Dosage
First-Line Options	
Amoxicillin	50?mg/kg/day up to 1?g bid
Clarithromycin	15?mg/kg/day up to 500?mg bid
Proton pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI)	1?mg/kg/day up to 20?mg bid
Amoxicillin	50?mg/kg/day up to 1?g bid
Metronidazole	20?mg/kg/day up to 500?mg bid

Proton pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI)	1?mg/kg/day up to 20?mg bid
Clarithromycin	15?mg/kg/day up to 500?mg bid
Metronidazole	20?mg/kg/day up to 500?mg bid
Proton pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI)	1?mg/kg/day up to 20?mg bid
Second-Line Options	
Bismuth subsalicylate	1 tablet (262?mg) qid *or* 15?mL (17.6?mg/mL qid)
Metronidazole	20?mg/kg/day up to 500?mg bid
Proton pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI) *plus* an additional antibiotic:	1?mg/kg/day up to 20?mg bid
Amoxicillin	50?mg/kg/day up to 1?g bid
or Tetracycline	50?mg/kg/day up to 1?g bid
or Clarithromycin	15?mg/kg/day up to 500?mg bid
Ranitidine bismuth-citrate	1 tablet qid
Clarithromycin	15? mg/kg/day up to 500?mg bid
Metronidazole	20?mg/kg/day up to 500?mg bid
From Gold BD, et al: Medical position statement:The North American Society for Pediatric Gastroenterology and Nutrition. Helicobacter pylori infection in children: Recommendations for diagnosis and treatment. J Pediatr Gastroenterol Nutr 2000;31:490–97.	

samples of exhaled air and thus is generally not suitable for very young patients. Concerns about exposure to radioactivity in growing individuals dictate that the test be performed with a nonradioactive isotope of carbon, such as ^{13}C. The methodology to analyze samples containing ^{13}C is not widely available, and detection can be expensive. Samples may need to be sent promptly to a reference laboratory. Prior antibiotic exposure and treatment with proton-pump inhibitors and other antacids can influence the test. A promising modality is the detection of *H. pylori* antigens in stool. This test is both sensitive and specific in children. Potential disadvantages include the need for a fresh stool specimen, reluctance of some patients to collect a stool sample, and prolonged shedding of *H. pylori* antigens for several weeks, even after successful eradication.

Treatment.

Treatment should be offered to patients with *H. pylori* who have ulcers (both duodenal and gastric) and have a history of ulcers, MALT lymphoma, and atrophic gastritis with intestinal metaplasia. In the absence of compelling data, the decision to treat the patient with gastritis but without ulcer rests with the clinician and the informed patient. The potential benefits of eradication have to be weighed against the side effects of therapy, its cost, and the emergence of resistant strains. Several treatment regimens are available to treat *H. pylori* infection. They consist of at least two antibiotics and a potent antacid (Table 316–1) given for 1–2 wk and result in eradication rates of more than 80% in adults.

316.1 Secondary or Stress (Peptic) Ulcer Disease

The underlying causes of secondary peptic ulcer disease are not fully understood; multiple factors that interfere with host defense mechanisms are involved. Mucosal blood flow is thought to be important in acute stress ulcers; other factors include mucus production, prostaglandin synthesis, acid production, and cell proliferation.

Clinical Manifestations.

In infants, stress ulcers are usually caused by sepsis, respiratory or cardiac insufficiency, trauma, or

dehydration. In older children, they are related to trauma or other life-threatening conditions. Stress ulcers and erosions associated with burns are also known as *Curling ulcers*. They are associated with normal gastric secretions and are common in patients with more than 25% body burns. *Cushing ulcers* follow head trauma or surgery and are associated with gastric hypersecretion. Most stress ulcers are asymptomatic, are often multiple, and may be terminal events. They can be associated with severe hemorrhage or perforation. Coagulopathy, hypotension, and need for mechanical respiration are important risk factors for overt clinically important gastrointestinal bleeding. Perforation and, more often, massive hemorrhage are often the initial symptoms.

Drug-Related Peptic Disease.

Nonsteroidal anti-inflammatory drugs, including aspirin, are common causes of gastritis and erosions. These drugs are thought to damage the mucosa by inhibiting prostaglandin synthesis, thereby inhibiting cell proliferation as well as mucosal bicarbonate and mucus secretion. Cyclooxygenase-2–specific inhibitors have a lower incidence of gastric ulceration.

Alcohol and smoking are known to affect gastroduodenal mucosa adversely. Although results of studies are conflicting, a meta-analysis of available studies indicates a statistical association between corticosteroid use and ulcer disease in children. An inhibitory effect on local production of mucus and prostaglandin is postulated. Other agents that may rarely cause gastritis include iron, calcium salts,

potassium chloride, and antibiotics, including chloramphenicol, penicillins, tetracyclines, and cephalosporins.

Treatment.

Treatment of secondary ulcers is similar to that of primary ulcers. The inciting cause should be removed if possible. Bleeding and, less often, perforation are common presentations and must be addressed immediately. Maintaining gastric pH at more than 3.5 in critically ill patients helps to prevent ulcer formation. Control of gastric acidity is a cornerstone of continuing therapy and should continue for 6 wk if the patient has active disease.

Antacids have been used to neutralize acid once it is secreted. The buffering ability of antacids varies, as do recommendations for their use. The aim is to increase the pH to more than 5. The full adult dose of the concentrated liquids is 15?mL per dose. The optimal pediatric dose of antacids is controversial and varies with acid secretion and the buffering capacity of the antacid. Doses of as much as 1?mL/kg/dose have been recommended. Most antacids are mixtures of magnesium and aluminum salts. The magnesium ion causes diarrhea, whereas the aluminum salts may cause constipation. Aluminum hydroxide binds with dietary phosphates and interferes with their absorption. If large doses of aluminum hydroxide are used over a period of time, complications of phosphate depletion and aluminum toxicity including anorexia, osteomalacia, and osteoporosis may occur. Patients with renal disease are especially prone to aluminum toxicity. Calcium antacids can cause increased acid secretion after the buffering effect has stopped.

Histamine (H_2)-receptor blockers that suppress acid secretion are widely used even though they are not approved for children. Cimetidine (20–40?mg/kg/24?hr in four doses) and ranitidine (4–6?mg/kg/24?hr in two doses) are the most frequently used liquid preparations. They are rapidly absorbed and may be taken with meals. They can also be administered intravenously or added to parenteral nutrition solutions.

Hydrogen pump inhibitors (e.g., omeprazole and lansoprazole) are the most potent inhibitors of gastric acid secretion and have raised concerns about achlorhydria-related bacterial overgrowth. In adults, healing of ulcers occurs with 4 wk of therapy; hydrogen pump inhibitors are a component of several schemes to eradicate *H. pylori.*

Sucralfate forms a white pastelike substance in an acid environment that adheres to inflamed mucosa and ulcers. Experience in children is limited. The adult dose is 10?mL (1?g) of the suspension four times a day on an empty stomach.

Misoprostol, a prostaglandin analogue, has been shown in adults to be effective in preventing and treating ulcers associated with the use of nonsteroidal anti-inflammatory drugs. Its use is limited by gastrointestinal side effects (abdominal pain, diarrhea). Studies in adults indicate that omeprazole is superior in treating erosions and ulcers associated with the use of nonsteroidal anti-inflammatory drugs. Octreotide reduces splanchnic blood flow and may stop active bleeding. Endoscopy can be used therapeutically to control bleeding not responding to medical therapy.

316.2 Zollinger-Ellison Syndrome

This rare syndrome can cause multiple recurrent duodenal and jejunal ulcers and is occasionally associated with diarrhea. Gastric secretion is markedly stimulated by serum gastrin and other hormones secreted by an islet cell tumor or hypertrophy. Hypergastrinemia, albeit lower than Zollinger-Ellison syndrome, may be noted in pyloric stenosis, short bowel syndrome, hyperparathyroidism, pheochromocytoma, and multiple endocrine neoplasia. Therapy with H_2 -receptor blockers or omeprazole can control gastric acid secretion and can improve symptoms when these slow-growing tumors cannot be entirely removed.

Chapter 317 - Inflammatory Bowel Disease

Jeffrey Hyams

The term *inflammatory bowel disease* (IBD) is used to represent two distinctive disorders of idiopathic chronic intestinal inflammation: Crohn disease and ulcerative colitis. Their respective etiologies are poorly understood, and both disorders are characterized by unpredictable exacerbations and remissions. The most common time of onset of IBD is during adolescence and young adulthood. A bimodal distribution has been shown with an early onset at 15–25 yr of age and a second smaller peak at 50–80 yr of age. Nonetheless, IBD may begin as early as the 1st yr of life. IBD is more common in urban areas than in rural areas. In developed countries, these disorders are the major causes of chronic intestinal inflammation in children beyond the 1st few yr of life.

Both *genetic and environmental influences* are involved in the pathogenesis of IBD. The incidence among Jews is high but varies geographically. Although incidence rates are low among blacks in Africa, in the United States they are similar to those of whites. The prevalence of Crohn disease in the United States is much lower for Hispanics and Asians than for whites and blacks. The risk of IBD in family members of an affected individual has been reported in the range of 7–22%; a child whose parents both have IBD has a greater than 35% chance of acquiring the disorder. Relatives of an individual with ulcerative colitis have a greater risk of acquiring ulcerative colitis than Crohn disease, whereas relatives of an individual with Crohn disease have a greater risk of acquiring this disorder; the two diseases may occur in the same family. The risk of occurrence of IBD among relatives of individuals with Crohn disease is somewhat greater than for individuals with ulcerative colitis. Within a family, Crohn disease may demonstrate anticipation, developing at an earlier age among the 2nd generation.

The importance of genetic factors in the development of IBD is noted by a higher chance that both twins will be affected if they are monozygotic rather than dizygotic. The concordance rate in twins is higher in Crohn disease than in ulcerative colitis. Genetic disorders that have been associated with IBD include Turner syndrome, the Hermansky-Pudlak syndrome, glycogen storage disease type Ib, and various immunodeficiency disorders. It has been suggested that the susceptibility loci for Crohn disease may exist on chromosomes 5 and 16. A possible gene on

chromosome 6, *NOD2* (also called *CARD15*—capase activation and recruitment domain), is expressed in macrophages and may be involved in bacterial lipopolysaccharide–host interactions. *NOD2*-positive patients that have homozygous mutations have a 20-fold risk of Crohn disease. Only 20% of patients are homozygous for *NOD2* variants. A perinuclear antineutrophil antibody (pANCA) is found in about 70% of individuals with ulcerative colitis compared with less than 20% of those with Crohn disease and is believed to represent a marker of genetically controlled immunoregulatory disturbance.

Environmental factors are also important and presumably explain discordance among twins and changes in risk among the same race in different geographic regions; the precise factors remain unknown. Individuals migrating to developed countries often appear to acquire the higher rates of IBD associated with these regions. Cigarette smoking is a risk factor for Crohn disease but paradoxically protects against ulcerative colitis. No specific infectious agent has been reproducibly associated with IBD.

An abnormality in intestinal mucosal immunoregulation may be of primary importance in the pathogenesis of IBD. The gut is under constant immunologic stimulation from microbial agents and dietary antigens. In response, the mucosa normally displays “physiologic” inflammation. In IBD, the mechanisms that keep “physiologic” inflammation in check fail and pathologic inflammation ensues. It is not clear if this represents an abnormal response to customary enteric antigens or a normal response to an as yet unidentified microbe. Mediators of inflammation (cytokines, arachidonic acid metabolites, reactive oxygen metabolites, growth factors) are involved, leading to tissue destruction and remodeling with fibrosis. Most therapies are aimed at interfering with these mediators.

It is usually possible to distinguish between ulcerative colitis and Crohn disease by the clinical presentation and radiologic, endoscopic, and histopathologic findings (Table 317–1). It is not possible to make a definitive diagnosis in about 10% of individuals with chronic colitis; this disorder is called *indeterminate colitis*. Occasionally, a child initially believed to have ulcerative colitis on the basis of clinical findings is subsequently diagnosed with Crohn colitis. The treatments of Crohn disease and ulcerative colitis overlap.

Extraintestinal manifestations occur slightly more commonly with Crohn disease than with ulcerative colitis. Growth retardation may be seen in 15–35% of individuals with Crohn disease at diagnosis. Of the extraintestinal manifestations that occur with IBD, joint, skin, eye, mouth, and hepatobiliary involvement tend to be associated with colitis, whether ulcerative or Crohn colitis. For some manifestations, activity correlates with activity of the bowel disease, including peripheral arthritis, erythema nodosum, and anemia. Activity of pyoderma gangrenosum correlates less well with activity of the bowel disease, whereas activities of sclerosing cholangitis, ankylosing spondylitis, and sacroiliitis do not correlate with intestinal disease. Arthritis occurs in three patterns: migratory peripheral arthritis involving primarily large joints, ankylosing spondylitis, and sacroiliitis. The peripheral arthritis of IBD tends to be nondestructive. Ankylosing spondylitis begins in the 3rd decade and occurs most commonly in individuals with ulcerative colitis who have the human leukocyte antigen B27 phenotype.

TABLE 317-1 -- **Comparison of Crohn Disease and Ulcerative Colitis**

Feature	Crohn Disease	Ulcerative Colitis
Rectal bleeding	Sometimes	Common
Diarrhea	Variable	Common
Abdominal pain	Common	Variable
Abdominal mass	Common	Not present
Growth failure	Common	Variable
Perianal disease	Common	Unusual
Rectal disease	Occasional	Universal
Pyoderma gangrenosum	Rare	Present
Erythema nodosum	Common	Less common
Mouth ulceration	Common	Rare
Thrombosis	Less common	Present
Colonic disease	50–75%	100%
Ileal disease	Common	None except backwash ileitis
Stomach-esophageal disease	Uncommon	None
Strictures	Common	Unusual
Fissures	Common	None
Fistulas	Common	Unusual
Toxic megacolon	None	Present
Sclerosing cholangitis	Less common	Present
Risk for cancer	Increased	Greatly increased
Discontinuous (skip) lesions	Common	Not present
Transmural involvement	Common	Unusual
Crypt abscesses	Less common	Common

Granulomas	Common	Unusual
Linear ulcerations	Uncommon	Common
Perinuclear antineutrophil cytoplasmic antibodies (pANCA)	Uncommon	Common
Anti–*Saccharomyces cerevisiae* antibodies	Common	Uncommon

Symptoms include low back pain and morning stiffness; back, hips, shoulders, and sacroiliac joints are typically affected. Isolated sacroiliitis is usually asymptomatic but is common when a careful search is performed. Among the skin manifestations, erythema nodosum is most common. Individuals with erythema nodosum or pyoderma gangrenosum have a high likelihood of having arthritis as well. Glomerulonephritis and a hypercoagulable state are other rare manifestations that occur in childhood. Cerebral thromboembolic disease has been described in children with IBD. Uveitis occurs in about 5% of children with IBD and is usually asymptomatic and transient; its occurrence does not correlate with activity of bowel disease.

317.1 Chronic Ulcerative Colitis

Ulcerative colitis, an idiopathic chronic inflammatory disorder, is localized to the colon and spares the upper gastrointestinal tract. Disease usually begins in the rectum and extends proximally for a variable distance. When it is localized to the rectum, the disease is ulcerative proctitis, whereas disease involving the entire colon is pancolitis. The former disorder is less likely to be associated with systemic manifestations, although it may be less responsive to treatment than more diffuse disease. About 30% of children who present with ulcerative proctitis experience proximal spread of the disease. Ulcerative colitis has rarely been noted to present in infancy. Dietary protein intolerance may be easily misdiagnosed as ulcerative colitis in this age group. Dietary protein intolerance (e.g., cow's milk protein) is a transient disorder; symptoms are directly associated with the intake of the offending antigen.

The incidence of ulcerative colitis has remained constant, in contrast to an increase in Crohn disease, but varies with country of origin. Incidence rates are highest in northern European countries and the United States (15/100,000) and lowest in Japan and South Africa (1/100,000). The incidence of ulcerative colitis in Israel varies with the country of origin; those born in Asia or Africa have the lowest risk. The prevalence of ulcerative colitis in northern European countries and the United States varies from 100–200/100,000 population. Men are slightly more likely to acquire ulcerative colitis than are women; the reverse is true for Crohn disease.

Clinical Manifestations.

Blood in the stool and diarrhea are the typical presentation of ulcerative colitis. Constipation may be observed in those with proctitis. Symptoms such as tenesmus, urgency, cramping abdominal pain (especially with bowel movements), and nocturnal bowel movements suggest more extensive disease. The mode of onset may range from insidious with gradual progression of symptoms to fulminant. Fever, severe anemia, hypoalbuminemia, leukocytosis, and greater than five bloody stools per day for 5 days is what defines fulminant colitis. Chronicity is an important part of the diagnosis; it is difficult to know whether one is dealing with a subacute, transient infectious colitis or ulcerative colitis when a child has had 1–2 wk of symptoms. Symptoms beyond this duration often prove to be secondary to IBD. Anorexia, weight loss, and growth failure may be present, although these complications are more typical of Crohn disease.

Extraintestinal manifestations that tend to occur more commonly with ulcerative colitis than with Crohn disease include pyoderma gangrenosum, sclerosing cholangitis, chronic active hepatitis, and ankylosing spondylitis. Any of the extraintestinal disorders described previously for IBD may occur with ulcerative colitis. Iron deficiency may result from chronic blood loss as well as decreased intake. Folate deficiency is unusual but may be accentuated in children treated with sulfasalazine, which interferes with folate absorption. Chronic inflammation and the elaboration of a variety of inflammatory cytokines may interfere with erythropoiesis and result in the anemia of chronic disease. Secondary amenorrhea is common during periods of active disease in older girls.

The clinical course of ulcerative colitis is marked by exacerbations, often without apparent explanation. The disease may be quieted with medication, but eventually it recurs. After initial symptoms, about 5% of children with ulcerative colitis have a prolonged remission (>3?yr). About 25% of children presenting with severe ulcerative colitis will require colectomy within 5 years of diagnosis, compared with only 5% of those presenting with mild disease. It is important to consider the possibility of enteric infection with recurrent symptoms; these infections may mimic a flare-up or actually provoke a recurrence. The use of nonsteroidal anti-inflammatory drugs is considered by some to predispose to exacerbation.

It is generally believed that the risk of colon cancer begins to increase after 8–10 yr of disease and may then increase by 0.5–1% per yr. The risk is delayed by about 10 yr in individuals with colitis limited to the descending colon. Proctitis alone is associated with virtually no increase in risk over the general population. Because colon cancer is usually preceded by changes of mucosal dysplasia, it is recommended that patients who have had ulcerative colitis for more than 10 yr be screened with colonoscopy and biopsy every 1–2?yr. Although this is the current standard of practice it is not clear if morbidity and mortality are changed by this approach. Two competing concerns about this plan of management remain unresolved: (1) the original studies may have overestimated the risk of colon cancer and, therefore, the need for surveillance has been overemphasized and (2) screening for dysplasia may not be adequate for the prevention of colon cancer in ulcerative colitis if some cancers are not preceded by dysplasia.

Differential Diagnosis.

The major conditions to exclude are infectious colitis, allergic colitis, and Crohn colitis. Every child with a new diagnosis of ulcerative colitis should have stool cultured for enteric pathogens, stool evaluation for ova and parasites, and perhaps

serologic studies for amebae (Table 317–2). In the setting of antibiotic use, pseudomembranous colitis secondary to *Clostridium difficile* should be considered. The most difficult distinction is from Crohn disease because the colitis of Crohn disease may initially appear identical to that of ulcerative colitis. The gross appearance of the colitis or development of small bowel disease eventually leads to the correct diagnosis; this may occur years after the initial presentation.

At the onset, the colitis of hemolytic-uremic syndrome may be identical to that of early ulcerative colitis. Ultimately, signs of microangiopathic hemolysis (the presence of schistocytes on blood smear), thrombocytopenia, and subsequent renal failure should confirm the diagnosis of hemolytic-uremic syndrome. Although Henoch-Schönlein purpura may present as abdominal pain and bloody stools, it is not usually associated with colitis. Behçet syndrome can be distinguished by its typical features (see Chapter 151 and Chapter 317.3). Other considerations are radiation proctitis, viral colitis in immunocompromised individuals, and ischemic colitis. In infancy, dietary protein intolerance may be confused with ulcerative colitis, although this disorder is a transient problem that resolves on removal of the offending protein. Hirschsprung disease may produce a colitis before or within months after surgical correction; this is unlikely to be confused with ulcerative colitis.

Diagnosis.

The diagnosis of ulcerative colitis or ulcerative proctitis requires a typical presentation in the absence of an identifiable specific cause (Box 317–1 ; also see Table 317–2) and typical endoscopic and histologic findings (see Table 317–1). One should be hesitant to make a diagnosis of ulcerative colitis in a child who has experienced symptoms for fewer than 2–3 wk until infection has been excluded. When the diagnosis is suspected in a child with subacute symptoms, the physician should make a firm diagnosis only when there is evidence of chronicity

TABLE 317.1-2

Agent	Manifestations	Diagnosis	Comments
Bacterial			
Campylobacter jejuni	Acute diarrhea, fever, fecal blood, and leukocytes	Culture	Common in adolescents, may relapse
Yersinia enterocolitica	Acute?diarrhea, right lower quadrant pain, mesenteric adenitis—pseudoappendicitis, fecal blood, and leukocytes	Culture	Common in adolescents as FUO, weight loss, abdominal pain
	Extraintestinal manifestations, mimics Crohn disease		
Clostridium difficile	Postantibiotic onset, watery?bloody diarrhea, pseudomembrane on sigmoidoscopy	Cytotoxin assay	May be nosocomial Toxic megacolon possible
Escherichia coli 0157:H7	Colitis, fecal blood, abdominal pain	Culture and typing	Hemolytic-uremic syndrome
Salmonella	Watery?diarrhea, food borne, fecal leukocytes, fever, pain, cramps	Culture	Usually acute
Shigella	Watery?diarrhea, fecal leukocytes, fever, pain, cramps	Culture	Dysentery symptoms
Edwardsiella tarda	Bloody diarrhea, cramps	Culture	Ulceration on endoscopy
Aeromonas hydrophila	Cramps, diarrhea, fecal blood	Culture	May be chronic Contaminated drinking water
Plesiomonas	Diarrhea, cramps	Culture	Shellfish source
Tuberculosis	Rarely bovine, now *Mycobacterium tuberculosis* Ileocecal area, fistula formation	Culture, PPD, biopsy	May mimic Crohn disease
Parasites			
Entamoeba histolytica	Acute bloody diarrhea and liver abscess, colic	Trophozoite in stool, colonic mucosal flask ulceration, serologic tests	Travel to endemic area
Giardia lamblia	Foul-smelling, watery diarrhea, cramps, flatulence, weight loss; no colonic involvement	“Owl”-like trophozoite and cysts in stool; rarely duodenal intubation	May be chronic
AIDS-Associated Enteropathy			
Cryptosporidium	Chronic diarrhea, weight loss	Stool microscopy	Mucosal findings not like IBD
Isospora belli	As in *Cryptosporidium*		Tropical location
Cytomegalovirus	Colonic ulceration, pain, bloody diarrhea	Culture, biopsy	

FUO = fever of unknown origin; PPD = purified protein derivative; AIDS = acquired immunodeficiency syndrome; IBD = inflammatory bowel disease.

on colonic biopsy. Laboratory studies may demonstrate evidence of anemia (either iron deficiency or the anemia of chronic disease) or hypoalbuminemia. Although the sedimentation rate is often elevated, it may be normal even with fulminant colitis.

Typhlitis

Hirschsprung colitis

Intestinal lymphoma

Laxative abuse

AIDS = acquired immunodeficiency syndrome; SLE = systemic lupus erythematosus.

An elevated white blood cell count is usually seen only with more severe colitis.

Findings of ulcerative colitis can be identified by endoscopic and histologic examination of the colon. Barium enema has no place in the diagnosis of this disorder. Classically, disease starts in the rectum with a gross appearance characterized by erythema, edema, loss of vascular pattern, granularity, and friability. There may be a “cut off” demarcating the margin between inflammation and normal colon, or the entire colon may be involved. There may be some variability in the intensity of inflammation even in those areas involved. One can use flexible sigmoidoscopy to confirm the diagnosis or colonoscopy to evaluate the extent of disease and to rule out evidence of Crohn colitis. A colonoscopy should *not* be performed when fulminant colitis is suspected because of the risk of provoking toxic megacolon or causing a perforation during the procedure. The degree of colitis can be evaluated by the gross appearance of the mucosa. Despite the name, one does not generally see discrete ulcers, which would be more suggestive of Crohn colitis. The endoscopic findings of ulcerative colitis result from microulcers, which give the appearance of a diffuse abnormality. With very severe chronic colitis, pseudopolyps may be seen. Biopsy of involved bowel demonstrates evidence of acute and chronic mucosal inflammation. Typical findings are cryptitis, crypt abscesses, separation of crypts by inflammatory cells, foci of acute inflammatory cells, edema, mucus depletion, and branching of crypts. The last finding is a feature not seen in infectious colitis. Granulomas, fissures, or full-thickness involvement of the bowel wall (usually on surgical rather than endoscopic biopsy) suggest Crohn disease. Rectal biopsy can also distinguish chronic IBD from acute self-limiting colitis.

Perianal disease, with the exception of mild local irritation or anal fissures associated with diarrhea, should make one think of Crohn disease. Plain radiographs of the abdomen may demonstrate loss of haustral markings in an air-filled colon or marked

dilatation with toxic megacolon. With severe colitis, the colon may become dilated; a diameter of greater than 6?cm, determined radiographically, in an adult suggests toxic megacolon. If it is necessary to examine the colon radiologically in a child with severe colitis (to evaluate the extent of involvement or to try to rule out Crohn disease), it is sometimes helpful to perform an upper gastrointestinal contrast series with small bowel follow-through and then look at delayed films of the colon. A barium enema is contraindicated in the setting of a potential toxic megacolon.

Treatment.

A medical cure for ulcerative colitis is not available; treatment is aimed at controlling symptoms and reducing the risk of recurrence. The intensity of treatment varies with the severity of the symptoms. Twenty to 30% of individuals with ulcerative colitis have spontaneous improvement in symptoms. The first drug class to be used with mild colitis is an aminosalicylate. Sulfasalazine is composed of a sulfur moiety linked to the active ingredient 5-aminosalicylate. This linkage prevents the premature absorption of the medication in the upper gastrointestinal tract, allowing it to reach the colon, where the two components are separated by bacterial cleavage. The dose of sulfasalazine is 50–75?mg/kg/24?hr (divided into two to four doses). Generally, the dose is not more than 2 to 3?g/24?hr. It is recommended that the dosage gradually increase to full dose over the 1st wk of treatment to avoid gastrointestinal symptoms (e.g., nausea and abdominal pain) and headache and to detect sulfa hypersensitivity. Onset of action may take several weeks. Sulfasalazine treats colitis; recurrences may be prevented with its use. It is recommended that the medication be continued even when the disorder is in remission. Hypersensitivity to the sulfa component is the major side effect of sulfasalazine and may occur in 10–20% of individuals. Other less allergenic preparations of 5-aminosalicylate (mesalamine, 40–60?mg/kg/day) have been shown to treat ulcerative colitis and prevent recurrences with efficacy equal to that of sulfasalazine.

Perhaps 10–20% of individuals who have an allergic reaction to sulfasalazine will have a similar reaction to another 5-aminosalicylate product. On rare occasions, these medications cause exacerbation of colitis. Aminosalicylate may also be given in enema form and is especially useful for proctitis. Hydrocortisone enemas (100?mg) are used to treat proctitis as well. Either form of enema may be administered to older children and is given once a day (usually bedtime) for 2–3 wk. Many children prefer oral medication to enemas.

Children with moderate to severe pancolitis or colitis that is unresponsive to 5-aminosalicylate therapy should be treated with oral corticosteroids, most commonly prednisone. The usual starting dose of prednisone is 1–2?mg/kg/24?hr (40–60?mg maximal dose). If symptoms are not severe, this medication may be given in a single morning dose to lessen adrenal suppression. With severe colitis, the dose may be divided twice daily and may be given intravenously. The goal is to taper to an alternate-day dose within 1–3 mo. Persistence of symptoms despite steroid treatment or the inability to taper the dose is an indication for the use of other medications or for surgical management. Prolonged use of daily steroids beyond this period is to be avoided because of the many side effects, including growth retardation, adrenal suppression, cataracts, osteopenia, aseptic necrosis of the head of the femur, glucose intolerance, risk of infection, and cosmetic effects. With medical management, most children are in remission within 3 mo; however, 5–10% continue to have symptoms unresponsive to treatment beyond 6 mo. Many children with disease requiring frequent corticosteroid therapy are started on immunomodulators such as azathioprine (1.5–2.5?mg/kg/day) or 6-mercaptopurine (1–1.5?mg/kg/day). Uncontrolled data suggest a corticosteroid-sparing effect in many treated individuals. Cyclosporine, which has been shown to be associated with improvement in many children with severe symptoms, does not appear to change the natural history of the disease. Anecdotal observations suggest a potential role for infliximab, a chimeric monoclonal antibody to tumor necrosis factor-a, in fulminant colitis.

Colectomy is performed for intractable disease, complications of therapy, and fulminant disease that is unresponsive to medical management. No clear benefit of the use of total parenteral nutrition or a continuous enteral elemental diet in the treatment of severe ulcerative colitis has been noted. Nevertheless, parenteral nutrition is often used so that the patient will be nutritionally ready for surgery if medical management fails. With any medical treatment for ulcerative colitis, one should always weigh the risk of the medication or therapy against the fact that colitis may be successfully treated surgically.

Surgical treatment for intractable or fulminant colitis is total colectomy. The optimal approach is to combine colectomy with an endorectal pull-through. In this procedure, the surgeon retains a segment of distal rectum and strips the mucosa from this region. The distal ileum is pulled down and sutured at the internal anus with a J pouch created from ileum immediately above the rectal cuff. This procedure allows the child to maintain continence. Commonly, a temporary ileostomy is created to protect the delicate anastomosis between the sleeve of the pouch and the rectum. The ileostomy is usually closed within several months, restoring bowel continuity. At that time stool frequency is often increased but may be improved with loperamide. The major complication of this operation is “pouchitis,” which is a chronic inflammatory reaction in the pouch, leading to bloody diarrhea, abdominal pain, and occasionally low-grade fever. The cause of this complication is unknown, although it is more frequent when the ileal pouch has been constructed for ulcerative colitis than for other indications (familial polyposis coli). Pouchitis is seen in 30–40% of patients who had ulcerative colitis. It commonly responds to treatment with oral metronidazole.

The concept that ulcerative colitis is primarily a psychogenic disorder is false. However, emotional stresses may contribute to exacerbations. Difficulty adjusting to a chronic disorder is common, and distorted body image should be considered when evaluating the psychologic profile of a child with this disorder. Psychosocial support is an important part of therapy for this disorder. This may include adequate discussion of the disease manifestations and management between patient and physician, psychologic counseling for the child when necessary, and family support from a social worker or family counselor. Patient support groups have proved helpful for some families. Children with ulcerative colitis should be encouraged to participate fully in age-appropriate activities; however, activity may need to be reduced during periods of disease exacerbation.

Prognosis.

The course of ulcerative colitis is marked by remissions and exacerbations. Most children with this disorder respond initially to medical management. Many children with mild manifestations continue to respond well to medical management and may stay in remission on a prophylactic 5-aminosalicylate preparation for long periods. However, an occasional child with mild onset experiences intractable symptoms at a later time. Beyond the 1st decade of disease, the risk of development of colon cancer begins to increase rapidly. The risk of colon cancer may be diminished with surveillance colonoscopies beginning after 8–10 yr of disease. Detection of significant dysplasia on biopsy would prompt colectomy.

317.2 Crohn Disease (Regional Enteritis, Regional Ileitis, Granulomatous Colitis)

Crohn disease, an idiopathic, chronic inflammatory disorder of the bowel, involves any region of the alimentary tract from the mouth to the anus. Although there are many similarities between ulcerative colitis and Crohn disease, there are also major differences in the clinical course and distribution of the disease in the gastrointestinal tract (see Table 317–1). The inflammatory process tends to be eccentric and segmental, often with skip areas (normal regions of bowel between inflamed areas). Although inflammation in ulcerative colitis is limited to the mucosa (except in toxic megacolon), gastrointestinal involvement in Crohn disease is transmural. Among children with Crohn disease, the initial presentation most commonly involves ileum and colon (ileocolitis) but may involve the small bowel alone in about 30% (70% of these patients have terminal ileitis alone) or colon alone in 10%–15%. Upper gastrointestinal involvement (esophagus, stomach, duodenum) is seen in up to 30% of children. As with ulcerative colitis, Crohn disease tends to have a bimodal age distribution, with the 1st peak beginning in the late teens. Diagnosis before 20 yr of age is associated with a greater chance of small bowel disease, development of stricture, and eventual need for surgery when compared with diagnosis after 40?yr. Likelihood of Crohn disease in family members is doubled with early diagnosis.

The incidence of Crohn disease has been increasing over the past 10?yr, whereas that of ulcerative colitis has been stable. The reported incidence of Crohn disease is about 3–4/100,000, and the prevalence is 30–100/100,000. The prevalence of Crohn disease in whites and blacks appears to be 3–10 times that of Hispanics and Asians living in the United States.

Clinical Manifestations.

Crohn disease presents in many forms; the manifestations tend to be dictated by the region of bowel involved, the degree of inflammation, and the presence of complications such as stricture or fistula. Children with ileocolitis typically have cramping, abdominal pain, and diarrhea, sometimes with blood. Ileitis may present as right lower quadrant abdominal pain alone. Crohn colitis may be associated with bloody diarrhea, tenesmus, and urgency. Systemic signs and symptoms are more common in Crohn disease than in ulcerative colitis. Fever, malaise, and easy fatigability are common. Growth failure with delayed bone maturation and delayed sexual development may precede other symptoms by 1 or 2 yr and are at least twice as likely to occur with Crohn as with ulcerative colitis. Children may present with growth failure as the only manifestation of Crohn disease. Growth retardation is associated with a decrease in lean body mass but preservation of body fat; enteric protein loss and the rate of body protein turnover are increased. Primary or secondary amenorrhea occurs frequently. In contrast to ulcerative colitis, perianal disease is common (tags, fistula, abscess). Gastric or duodenal involvement may be associated with recurrent vomiting and epigastric pain. Partial small bowel obstruction, usually secondary to narrowing of the bowel lumen from inflammation or stricture, may cause symptoms of cramping abdominal pain (especially with meals),

borborygmus, and intermittent abdominal distention. Stricture should be suspected if the child notes relief of symptoms in association with a sudden sensation of gurgling of intestinal contents through a localized region of the abdomen. Ureteral obstruction (usually right-sided) secondary to extension of the inflammatory process is a rare complication of Crohn disease.

Enteroenteric or enterocolonic fistulas (between segments of bowel) are often asymptomatic but may contribute to malabsorption if they have high output or result in bacterial overgrowth. Enterovesical fistulas (between bowel and urinary bladder) originate from ileum or sigmoid colon and present as signs of urinary infection, pneumaturia, or fecaluria. Enterovaginal fistulas originate from the rectum, cause feculent vaginal drainage, and are difficult to manage. Enterocutaneous fistulas (between bowel and abdominal skin) often are caused by prior surgical anastomoses with leakage. Intra-abdominal abscess may be associated with fever and pain but may have relatively few symptoms. Hepatic or splenic abscess may occur with or without a local fistula. Anorectal abscesses often originate immediately above the anus at the crypts of Morgagni. The patterns of perianal fistulas are complex because of the different tissue planes. Perianal abscess is usually painful, but perianal fistulas tend to produce fewer symptoms than might be anticipated. Purulent drainage is commonly associated with perianal fistulas. Psoas abscess secondary to intestinal fistula may present as hip pain, decreased hip extension (psoas sign), and fever.

Extraintestinal manifestations occur more commonly with Crohn disease than with ulcerative colitis; those that are especially associated with Crohn disease include oral aphthous ulcers, peripheral arthritis, erythema nodosum, digital clubbing, episcleritis, renal stones (uric acid, oxalate), and gallstones. Any of the extraintestinal disorders described in the section on IBD may occur with Crohn disease. The peripheral arthritis is nondeforming. In general, the occurrence of extraintestinal manifestations correlates with the presence of colitis. During periods of active disease, secondary amenorrhea is common in older girls.

Extensive involvement of small bowel, especially in association with surgical resection, may lead to short-bowel syndrome, which is rare in children. Complications of terminal ileal dysfunction or resection include bile acid malabsorption with secondary diarrhea and vitamin B_{12} malabsorption. Chronic steatorrhea may lead to oxaluria with secondary renal stones. The risk of cholelithiasis is also increased secondary to bile acid depletion.

A disorder with this diversity of manifestations can have a major impact on an affected child's lifestyle. Fortunately, the majority of children with Crohn disease are able to continue with their normal activities, having to limit activity only during periods of increased symptoms.

Differential Diagnosis.

As in patients with ulcerative colitis, the most common diagnoses to be distinguished from Crohn disease are the infectious enteropathies (in the case of Crohn disease: acute terminal ileitis, infectious colitis, enteric parasites, and periappendiceal abscess) (see Table 317–2 and Box 317–1). *Yersinia* may cause many of the radiologic and endoscopic findings in the distal small bowel that are seen in Crohn disease. The

symptoms of bacterial dysentery are more likely to be mistaken for ulcerative colitis than for Crohn disease. *Giardia* has been noted to produce a Crohn-like presentation including protein-losing enteropathy. Gastrointestinal tuberculosis is rare but can mimic Crohn disease. Foreign-body perforation of the bowel (toothpick) may mimic a localized region with Crohn disease. Small bowel lymphoma may mimic Crohn disease but tends to be associated with nodular filling defects of the bowel without ulceration or narrowing of the lumen. Bowel lymphoma is much less common in children than is Crohn disease. Recurrent functional abdominal pain may mimic the pain of small bowel Crohn disease. Lymphoid nodular hyperplasia of the terminal ileum (a normal finding) may be mistaken for Crohn ileitis. Right lower quadrant pain or mass with fever may be the result of periappendiceal abscess. This entity may occasionally be associated with diarrhea as well. Necrotizing jejunitis is a rare condition of transient, acute inflammation of jejunum (or less commonly ileum or colon), which may recur.

Growth failure may be the only manifestation of Crohn disease; other disorders such as growth hormone deficiency or gluten-sensitive enteropathy (celiac disease) must be considered. If arthritis precedes the bowel manifestations, an initial diagnosis of juvenile rheumatoid arthritis may be made. Refractory anemia may be the presenting feature and may be mistaken as a primary hematologic disorder. Leukemia may present with abdominal pain in association with an abnormal blood cell count and initially may be mistaken for Crohn disease. Chronic granulomatous disease of childhood may cause inflammatory changes in the bowel with granulomas seen at biopsy. Antral narrowing in this disorder may be mistaken for a stricture secondary to Crohn disease.

Diagnosis.

Crohn disease may present as a variety of symptom combinations. At the onset, symptoms may be subtle (growth retardation or abdominal pain alone); this explains why the diagnosis may not be made until 1 or 2 yr after the start of symptoms. The diagnosis of Crohn disease depends on finding typical clinical features of the disorder (history, physical examination, laboratory studies, and endoscopic or radiologic findings), ruling out specific entities that mimic Crohn disease, and demonstrating chronicity. The history may include any combination of abdominal pain (especially right lower quadrant), diarrhea, vomiting, anorexia, weight loss, growth retardation, and extraintestinal manifestations.

Children with Crohn disease often appear chronically ill. They commonly have weight loss and are often malnourished. Linear growth retardation frequently precedes clinical presentation by as much as 1–2?yr; this manifestation may not have been appreciated until the diagnosis is established. Children with Crohn disease often appear pale with decreased energy level and poor appetite; the latter finding sometimes results from an association between meals and abdominal pain or diarrhea. There may be abdominal tenderness that is either diffuse or localized to the right lower quadrant. A tender mass or fullness may be palpable in the right lower

quadrant. Perianal disease, when present, may be characteristic. Large anal skin tags (1–3?cm diameter) or perianal fistulas with purulent drainage are suggestive of Crohn disease. Digital clubbing, findings of arthritis, and skin manifestations may be present. A complete blood cell count commonly demonstrates an anemia, often with a component of iron deficiency. Although the sedimentation rate is often elevated, it may be normal; an elevated platelet count (>600,000/mm^3) is common. The white blood cell count may be normal or mildly elevated. The serum albumin level may be low, and the stool a_1 -antitrypsin level may be elevated, consistent with a protein-losing enteropathy. Anti-*Saccharomyces cerevisiae* antibodies are identified in 55% of children with Crohn disease but in only 5% of children with ulcerative colitis.

The small and large bowel should be examined in the child with suspected Crohn disease. The initial choice of colonoscopy or a radiologic study partly depends on the anticipated location of disease. For small bowel involvement, an upper gastrointestinal contrast examination with small bowel follow-through would be the initial study. A variety of findings may be apparent on radiologic studies. Plain films of the abdomen may be normal or may demonstrate findings of partial small bowel obstruction or thumbprinting of the colon wall. An upper gastrointestinal contrast study with small bowel follow-through may show aphthous ulceration and thickened, nodular folds as well as narrowing of the lumen anywhere in the gastrointestinal tract. Linear ulcers may give a cobblestone appearance to the mucosal surface. Bowel loops are often separated as a result of thickening of bowel wall and mesentery. Terminal ileum is most commonly involved. Diseased regions tend to be eccentric, and normal regions may be found between diseased segments (skip areas).

Other manifestations on radiographic studies that suggest more severe Crohn disease are fistulas between bowel (enteroenteric or enterocolonic), sinus tracts, and strictures. Following the flow of barium antegrade into the colon may reveal right-sided colonic disease. Ultrasonography and contrast CT are most useful in identifying intra-abdominal abscess. Thickened bowel wall may be seen on CT. MRI can localize areas of active bowel disease, although this study is probably no better for identifying an abscess. MRI is also useful in evaluating Crohn disease during pregnancy because it does not use ionizing radiation. Radionuclide scans utilizing white blood cells tagged with indium may help locate affected areas.

Colonoscopy with biopsy can be more helpful than radiologic or radionuclide studies in evaluating colon disease and in establishing a diagnosis. It is sometimes possible to enter the terminal ileum during colonoscopy; this maneuver may be helpful in clarifying an equivocal diagnosis of ileal Crohn disease. Findings on colonoscopy may include patchy, nonspecific inflammatory changes (erythema, friability, loss of vascular pattern), aphthous ulcers, linear ulcers, nodularity, and strictures. Findings on biopsy may be only nonspecific inflammatory changes. Noncaseating granulomas, similar to those of sarcoidosis, are the most characteristic histologic findings, although often they are not present. Transmural inflammation is also characteristic but can be identified only in surgical specimens.

Treatment.

Crohn disease cannot be cured by either medical or surgical therapy. The aim of treatment is to relieve symptoms and prevent complications of chronic inflammation (anemia, growth failure), prevent relapse, and, if possible, effect mucosal healing. The specific therapeutic modalities used depend on geographic localization of disease, severity of inflammation, age of the patient, and the presence of complications (abscess). For mild terminal ileal disease or mild Crohn disease of the colon, an initial trial of mesalamine (40–60?mg/kg/day, maximum 3?g) may be attempted. Specific pharmaceutical preparations have been formulated to release the active 5-ASA compound in the ileum and colon. Sulfasalazine may be effective for mild Crohn colitis but will not be helpful for small bowel disease. For more extensive or severe small bowel or colonic disease, most clinicians will initiate therapy with corticosteroids (prednisone, 1–2?mg/kg/day, maximum 40–60?mg). The goal is to taper to a single morning alternate-day dose as soon as the disease becomes quiescent. Typically, tapering can begin by 3–4 wk and continue over several months. Clinicians vary in their tapering schedules, but most will decrease the daily dose by 2.5–5?mg every 6–8 days until the daily dose is about 0.5?mg/kg, and then a similar decrease is effected on alternate days in 6–8 day cycles (e.g., 25?mg alternating with 20?mg for 8 days, followed by 25?mg alternating with 15?mg for 8 days, etc.). Eventually the prednisone is given on alternate days only and then that dose is tapered as tolerated. This approach is well tolerated, but the disease may flare

during the process. Continuing daily or alternate-day prednisone as maintenance therapy to prevent relapse has not been shown to be effective.

Growth is impaired with either active disease or daily corticosteroid therapy. Growth is not impaired by alternate-day therapy. Side effects of daily steroid treatment tend to occur more rapidly and be more severe when the serum albumin level is reduced. Steroid enemas have been used for distal colon disease. Budesonide is being tried in enema and oral form because of its lower potential for systemic side effects.

Unfortunately, up to 40% of children with Crohn disease will either become refractory to corticosteroid therapy or become dependent on daily dosing and quickly experience flare of the disease when the dose is decreased. Immunomodulators such as azathioprine (1.5–2.5?mg/kg/day) or 6-mercaptopurine (1.0–1.5?mg/kg/day) may be effective in some individuals who have a poor response to prednisone or who are steroid dependent. Because a beneficial effect of these drugs may be delayed for 3–6 mo after starting therapy they are not helpful acutely. The early use of these agents may decrease cumulative prednisone dosages over the first 1–2 yr of therapy. Infliximab (5?mg/kg given intravenously), a chimeric monoclonal antibody to tumor necrosis factor-a, will be associated with marked symptom improvement in 50–70% of patients and may serve as a bridge until the immunomodulators take effect. The durability of response to infliximab is variable and may be as short as 4–8 wk, making repeated dosing necessary in some patients. Side effects include allergic reactions, increased incidence of infections (especially tuberculosis), and the development of autoantibodies. Long-term safety of this biologic therapy appears good but awaits further study. A purified protein derivative (PPD) test for tuberculosis 1 should be done before starting infliximab.

There are several therapies available to treat perirectal fistula. Metronidazole

(10–20?mg/dL/day) is often effective, but long-term therapy can cause neuropathy with paresthesias requiring cessation of therapy. Azathioprine and 6-mercaptopurine have succeeded in this situation. Infliximab is also useful, although recurrence is common.

Nutritional therapy is an effective primary as well as adjunctive treatment. The enteral nutritional approach (elemental or polymeric diets) is both as rapid in onset of response and as effective as the other treatments. Others suggest prednisone is more effective for the acute control of disease. Because these diets are relatively unpalatable, they are administered via a nasogastric or gastrostomy infusion. With severe, acute disease, they may be given continuously as a 24-hr infusion; the treatment may then be cycled to overnight infusion at home. Repletion should be planned for ideal weight to allow for catch-up growth. Most children are hesitant to use nasogastric infusion, but once it is begun most find it is not difficult. The advantages are that it (1) is relatively free of side effects, (2) avoids the problems associated with corticosteroid therapy, and (3) simultaneously addresses the nutritional rehabilitation. Children may participate in normal daytime activities. A major disadvantage of this approach is similar to that of other therapies: early relapse on discontinuing treatment. In addition, perianal and colon disease does not respond well. For children with growth failure this approach may be ideal.

High-calorie oral supplements, although effective, often are not tolerated because of early satiety or exacerbation of symptoms (abdominal pain, vomiting, or diarrhea). Nonetheless, they should be offered to children whose weight gain is suboptimal. The continuous administration of nocturnal nasogastric feedings for chronic malnutrition and growth failure has been effective with a much lower risk of complications than parenteral hyperalimentation. Complex formula may be given at 500–1,000 kcal nightly; treatment with 50–80 kcal/kg/night monthly every 4 mo has been considered equally effective by some.

The initial onset or a recurrence of Crohn disease may be acute, with severe pain, anorexia, fever, abdominal tenderness, and an elevated white blood cell count. In this situation, it is difficult to rule out an infectious process involving the bowel wall (microperforation). In addition to the use of intravenous corticosteroids, broad-spectrum intravenous antibiotic coverage for bowel flora (gram-negative bacteria and anaerobes) should be started initially and discontinued only if it appears that there is not an infectious process. An ultrasonogram or contrast CT study of the abdomen is necessary to rule out an intra-abdominal abscess. The development of an enteroenteric or colonic fistula may be identified on CT, although it is best seen on a conventional small bowel contrast study.

Surgical therapy should be reserved for very specific indications. Recurrence rate after bowel resection is high (>50% by 5?yr); the risk of requiring additional surgery increases with each operation. Potential complications of surgery include development of fistula or stricture, anastomotic leak, postoperative partial small bowel obstruction secondary to adhesions, and short-bowel syndrome. Surgery is the treatment of choice with localized disease of small bowel or colon that is unresponsive to medical treatment, bowel perforation, fibrosed stricture with symptomatic partial small bowel obstruction, and intractable bleeding. Intra-abdominal or liver abscess may sometimes be successfully treated by ultrasonographic or CT-guided catheter drainage and concomitant intravenous antibiotic treatment. Open surgical drainage is necessary if this approach is not successful. Perianal abscess often requires drainage unless it drains spontaneously. In general, perianal fistulas should be managed medically. However, a severely symptomatic perianal fistula may require fistulotomy; this procedure should be considered only if the location allows the sphincter to remain undamaged. Growth retardation was once considered an indication for resection; without other indications, this approach has not been shown to be beneficial, and medical or nutritional therapy, or both, is preferred.

The surgical approach for Crohn disease is to remove as small a region of bowel as possible. There is no evidence that removing bowel up to margins that are free of histologic disease has a better outcome than removing only grossly involved areas. The latter approach reduces the risk of short-bowel syndrome. One approach to symptomatic small bowel stricture has been to perform a strictureplasty rather than resection. The surgeon makes a longitudinal incision across the stricture but then closes the incision with sutures in a transverse fashion. This is ideal for short strictures without active disease. The reoperation rate is no higher with this approach than with resection, whereas bowel length is preserved.

Severe perianal disease may be incapacitating and difficult to treat if unresponsive to medical management. Colon diversion may allow the area to be less active; but on reconnection of the colon, disease activity usually recurs. Therefore, surgical treatment of severe perianal disease may require colectomy. Procedures that create a continent ileostomy or endorectal pull-through are generally discouraged in Crohn disease because of the risk of recurrence of the disease in remaining bowel. With colectomy, a conventional ileostomy is performed.

Psychosocial issues for the child with Crohn disease include a sense of being different, concerns about body image, difficulty in not participating fully in age-appropriate activities, and family conflict brought on by the added stress of this disease. Social support is an important component of the management of Crohn disease. Parents are often interested in learning about other children with similar problems, but children may be hesitant to participate. Social support and individual psychologic counseling are important in the adjustment to a difficult problem at an age that by itself often has difficult adjustment issues. Patients who are socially “connected” fare better. Ongoing education about the disease is an important aspect of management

because children generally fare better if they understand and anticipate problems. The Crohn and Colitis Foundation of America has local chapters throughout the United States.

Prognosis.

Crohn disease is a chronic disorder that is associated with high morbidity but low mortality. Symptoms tend to recur despite treatment and often without apparent explanation. One exception is that symptoms of partial small obstruction may occur after a high-residue meal in the presence of a small bowel stricture. Weight loss and growth failure can usually be improved with treatment and attention to nutritional

needs. Up to 15% of individuals with early growth retardation secondary to Crohn disease have a permanent decrease in linear growth. Osteopenia is particularly common in those with chronic poor nutrition and frequent exposure to high doses of corticosteroids. Some of the extraintestinal manifestations may, in themselves, be major causes of morbidity, including sclerosing cholangitis, chronic active hepatitis, pyoderma gangrenosum, and ankylosing spondylitis.

The region of bowel involved may increase with time, although rapid progression typically occurs early and subsequently is slow. Complications of the inflammatory process tend to increase with time and include bowel strictures, fistulas, perianal disease, and intra-abdominal or retroperitoneal abscess. Nearly all individuals with Crohn disease eventually require surgery for one of its many complications; the rate of reoperation is high. The time between the onset of symptoms and the need for surgery appears to be shorter in children than in adults. Surgery is unlikely to be curative and should be avoided except for the specific indications noted previously. Repeated small bowel resection, which may be unavoidable, can lead to malabsorption secondary to short-bowel syndrome (see Chapter 320.7). Resection of terminal ileum may result in bile acid malabsorption with diarrhea and vitamin B_{12} malabsorption. The risk of colon cancer in individuals with long-standing Crohn colitis may approach that associated with ulcerative colitis, and screening colonoscopy after 10 years of colonic disease is indicated.

Despite these complications, most children with Crohn disease lead active, full lives with intermittent flare-up in symptoms.

317.3 Behçet Syndrome

Behçet syndrome is a systemic vasculitis that is rare in children (see Chapter 162). Aphthous stomatitis, erythema nodosum, and arthritis are among the most common manifestations. The ulcers are 2–10?mm in diameter and occur anywhere in the mouth or posterior pharynx; intestinal ulceration may mimic Crohn disease. The ulcers are covered by white-yellow membranes, have red borders, and are painful. Other signs are genital ulcers, central nervous system involvement, and myositis. Ocular findings (iridocyclitis) are less common in children than in adults. Immunosuppressive drugs have been used with mixed success. There appears to be significant familial aggregation.

Chapter 318 - Food Allergy (Food Hypersensitivity)

Jeffrey Hyams

Food allergy is a group of disorders in which symptoms result from immunologic responses to specific food antigens. Food allergy occurs in as many as 6% of children during the first 3 yr of life, including the 2–3% of infants and toddlers with cow's milk allergy. Reactions are classified as IgE mediated and non–IgE mediated. IgE-mediated reactions are caused by inflammatory mediators released when food antigen binds to specific IgE antibody on mast cells and basophils. These reactions are associated with rapid development of symptoms. Non–IgE-mediated reactions are cell mediated and develop over hours to days. For some clinical conditions there appear to be multiple mechanisms involved.

Clinical Manifestations.

Food antigen may provoke respiratory, skin, or gastrointestinal symptoms. Gastrointestinal manifestations can occur anywhere in the alimentary tract and often dominate. Behavioral manifestations have been described but are controversial.

IgE-Mediated Food Hypersensitivity

ORAL ALLERGY SYNDROME.

Contact with the allergen on the oropharynx causes itching or tingling and angioedema of the lips, tongue, palate, and throat. These symptoms may precede other IgE-mediated manifestations of food allergy. Allergy

to pollen (hay fever) is also common in these patients. Facial erythema from contact with citrus and tomato products is not considered an immune response.

GASTROINTESTINAL ANAPHYLAXIS.

Rapid onset of nausea, cramping abdominal pain, vomiting, or diarrhea, or a

combination of these conditions occurs after ingestion of an allergen. The most common proteins implicated include milk, egg, peanut, soy, cereal, and fish.

OTHER NONGASTROINTESTINAL MANIFESTATIONS.

These include cutaneous—urticaria, angioedema, and atopic dermatitis (eczema); respiratory—asthma and rhinoconjunctivitis; and systemic anaphylaxis. Life-threatening reactions typically are associated with ingestion of peanuts, nuts, fish, and shellfish. These subjects often have a concomitant history of asthma.

Mixed (IgE- and Non–IgE-Mediated) Food Hypersensitivity.

These disorders are characterized by intense eosinophilic infiltration of the specific organ involved. The inflammatory infiltrate may involve the mucosa, muscularis, or serosa of the stomach or small intestine. Eosinophilic infiltration of the muscularis leads to thickening and nodularity, causing symptoms of obstruction (e.g., pain and vomiting), whereas serosal infiltration leads to eosinophilic ascites. Many patients with these disorders respond to removal of certain dietary antigens from the diet (e.g., milk), whereas others require a more drastic whole protein restriction with the concomitant use of hydrolyzed protein or amino acid–based formulas. Occasional patients also require corticosteroid therapy.

ALLERGIC EOSINOPHILIC ESOPHAGITIS.

This disorder is characterized by intense eosinophilic infiltration of the esophageal mucosa. In infants and toddlers vomiting is the most common symptom, whereas in older children dysphagia and abdominal pain or heartburn are more common (see Chapter 305). Rarely esophageal strictures may be present in older children and adolescents. Clinicians mistakenly diagnose these patients with gastroesophageal reflux but they do not respond to usual therapies, and intraesophageal pH probe testing is normal. Treatment usually involves dietary modification in younger patients, with the occasional temporary need for an amino acid–based diet; older patients are usually treated with corticosteroids.

ALLERGIC EOSINOPHILIC GASTRITIS.

This disorder is more common in infancy and adolescence and presents as abdominal pain, vomiting, anorexia, hematemesis, poor weight gain, and, rarely, gastric outlet obstruction. It may mimic pyloric stenosis in young infants. Atopic features, elevated serum IgE levels, and peripheral eosinophilia are seen in about 50% of patients. Gastric biopsy reveals intense eosinophilic infiltration of the mucosa and submucosa, particularly in the antrum.

ALLERGIC EOSINOPHILIC GASTROENTEROCOLITIS.

These patients have similar symptoms to those described for allergic esophagitis and gastritis. Failure to thrive is common, and the majority of affected individuals have atopic symptoms. Marked protein-losing enteropathy may present as generalized edema and hypogammaglobulinemia.

Non–IgE-Mediated Disorders

ALLERGIC PROCTOCOLITIS.

Infants may present between 1 day and 3 mo of age with spots or streaks of blood and mucus in stool and occasional mild diarrhea. Increased numbers of white blood cells in stool and peripheral eosinophilia may be present. Typically, a patchy, mild colitis is present; nodular lymphoid hyperplasia occurs in about 25% of cases. Most often, proctocolitis results from hypersensitivity to cow's milk; soy sensitivity is less common. This disorder also occurs in exclusively breast-fed patients and occasionally abates with maternal diet modification with elimination of milk products. Non–breast-fed infants can be treated with protein hydrolysate formulas.

FOOD-INDUCED ENTEROCOLITIS.

Protracted vomiting and diarrhea begin between 1 wk and 3 mo of age. Less severe reactions can occur in older children and adults. Stools contain occult blood, neutrophils, and eosinophils. Jejunal biopsy demonstrates flattened villi, edema, and inflammatory cells. Symptoms resolve within 72?hr of removal of the offending food and recur within 1–6?hr of reintroduction. The blood neutrophil count increases by at least 3.5×10^9 /L at 4–6?hr after a food challenge. Older infants may develop a poorly characterized syndrome of anemia, hypoproteinemia, and failure to thrive when weaned from nursing or formula to ordinary cow's milk. Eosinophilia is common. Casein hydrolysate or amino acid–based formulas successfully treat most patients.

FOOD-INDUCED ENTEROPATHY.

Malabsorption, protracted diarrhea, vomiting, and failure to thrive caused by food hypersensitivity occur most often during the 1st mo of life. Small bowel biopsy shows patchy villus atrophy with mononuclear cell inflammatory response. Reaction to food challenge as well as resolution of symptoms on removal of the offending food may take several days to weeks.

CELIAC DISEASE (GLUTEN-SENSITIVE ENTEROPATHY) AND DERMATITIS HERPETIFORMIS.

Both entities occur as an immunologic response to gluten ingestion, and the two can occur together. See Chapter 320.8 .

PULMONARY HEMOSIDEROSIS (HEINER SYNDROME).

A combination of pulmonary infiltrates from pulmonary hemorrhage, gastrointestinal bleeding, iron-deficiency anemia, peripheral eosinophilia, and failure to thrive secondary to food intolerance (often cow's milk protein) resolves on removal of the offending food from the diet.

Diagnosis.

Food allergy is suspected when typical symptoms occur with the introduction of specific foods. Other nonallergic mechanisms of food intolerance should be ruled out (compromised digestive or absorptive processes, contamination with microbes or toxins, or pharmacologic activity of foods). Lactose intolerance should be considered when cow's milk allergy is suspected. Elimination diet and subsequent double-blind, placebo-controlled food challenge (DBPCFC) are the gold standard for diagnosis of food allergy. In DBPCFC, suspected foods are administered in capsules in progressively increasing amounts, alternating with placebo, and reactions are evaluated in a blinded fashion. Open food challenges, although commonly performed, are less reliable (except in young infants). Symptoms can be reproduced by DBPCFC in only 40% of children with suspected food allergy. When anaphylaxis has followed ingestion of a food, challenge should not be performed, and an allergist should evaluate the child.

The judicious use of a skin prick test or radioallergosorbent test (RAST) can be very useful in determining whether an IgE allergic reaction is the cause of a food allergy. Children can be tested for IgE reactions to foods at any age because IgE is made by 24 wk gestation. A negative IgE test, especially if the patient is older than 1 yr of age, is very accurate in predicting that the reaction is not IgE mediated. The significance of a positive IgE test has to be determined by the history and the age of the patient. A positive skin test is found in nearly 100% of children 3 yr of age or older who have a positive DBPCFC. Total-serum IgE is unreliable in diagnosing food allergy.

In infancy, hypersensitivity is most often associated with ingestion of cow's milk or soy protein. Although nursing may prevent the development of food allergy, manifestations of food allergy, especially proctocolitis, can occur while nursing. Cow's milk in the mother's diet is the most common identifiable cause of food-allergic reactions in nursing infants; reaction to peanut, soy, or egg in the mother's diet occurs less often.

Among infants and children with food allergy, 90% of reactions are to egg, milk, peanuts, soy, and wheat. Seventy-five per cent of children with proven food allergy react only to a single food. Children with allergic eosinophilic gastroenteritis are the exception, often reacting to multiple foods.

Treatment and Prognosis.

The only therapy proved effective for food allergy is an elimination diet. Most gastrointestinal manifestations resolve within several days, although some may take weeks (food-induced enteropathy). A child at risk for a severe and life-threatening IgE-mediated reaction should have access to injectable epinephrine and an antihistamine.

At least 30% of infants with cow's milk allergy also demonstrate sensitivity to soy protein. Generally, these infants improve with protein hydrolysate formula; less than 5% have persistent symptoms and these cases resolve with the use of amino acid–based formulas. Re-lactation is an alternative when cow's milk allergy presents early. About 50% of infants who experience proctocolitis while nursing improve with removal of cow's milk from the mother's diet. In the others, one must decide whether the symptoms are severe enough (anemia and hypoproteinemia) to warrant a change in the infant's diet to a protein hydrolysate formula.

Eighty-five per cent of infants with non–IgE-mediated food hypersensitivity to milk proteins no longer have symptoms on food challenge by 3 yr of age. Resolution of symptoms from cow's milk or soy protein hypersensitivity is common by 1 yr of age. When milk is reintroduced, only a teaspoon or less should be offered at first and then increased progressively over a few days if tolerated. Even older children and adults may lose their sensitivity to an offending food when it is eliminated from the diet for 1 to 2?yr. Symptoms from IgE-mediated allergy to peanut, nuts, fish, or shellfish are the exception and do not resolve.

Chapter 319 - Eosinophilic Gastroenteritis

Jeffrey Hyams

This entity consists of a group of rare and poorly understood disorders that have in common gastric and small intestine infiltration with eosinophils and peripheral eosinophilia. The esophagus and large intestine may also be involved. Tissue eosinophilic infiltration can be seen in mucosa, muscularis, or serosa. Mucosal involvement may produce nausea, vomiting, diarrhea, abdominal pain, gastrointestinal bleeding, protein- losing enteropathy, or malabsorption. Involvement of the muscularis may produce obstruction (especially of the pylorus), whereas serosal activity produces eosinophilic ascites.

This condition clinically overlaps the dietary protein hypersensitivity disorders of the small bowel and colon (see Chapter 318). Allergies to multiple foods are often seen, and serum IgE is commonly elevated. Peripheral eosinophilia is present in more than 50% of individuals with this disorder. The mucosal form is most frequent and is diagnosed by identifying large numbers of eosinophils in biopsy specimens of gastric antrum or small bowel.

The disease usually runs a chronic, debilitating course with sporadic severe exacerbations. Rare patients are helped by elimination diets or the use of cromolyn, but most require systemic administration of corticosteroids. Isolated eosinophilic esophagitis, unresponsive to gastroesophageal reflux therapy, may improve with an elimination diet; in the absence of stomach or small bowel involvement, this may be a separate entity.

Chapter 320 - Malabsorptive Disorders*

Manuel Garcia-Careaga
John A. Kerner

Intestinal malabsorption can be part of many childhood diseases. It is a condition rather than a diagnosis. Malabsorption may present as watery diarrhea, acidic diarrhea, or steatorrhea. The absence of diarrhea and even the presence of a normal stool do not rule out a malabsorptive disorder.

Malabsorptive syndromes are conditions that cause insufficient assimilation of ingested nutrients as a result either of maldigestion or of malabsorption (Table 320–1). Children with disorders that cause generalized defects in assimilation of nutrients tend to present with similar signs and symptoms: abdominal distention; pale, foul-smelling, bulky stools; muscle wasting; poor weight gain or weight loss; and growth retardation (Fig. 320–1).

Congenital disorders affecting individual intestinal digestive enzymes or transport processes have also been identified. Some of these disorders may present as early as the 1st wk of neonatal life and can be life threatening. The clinical features of these disorders typically differ from those of the generalized malabsorption syndromes. Some present without gastrointestinal symptoms (Table 320–2). The disaccharidase deficiencies are the most common of these entities.

320.1 Evaluation of Children with Suspected Intestinal Malabsorption

Clinical Manifestations.

Although many disorders of malabsorption are inherited, the child without a family history presents the greatest diagnostic challenge. Presentation of congenital disorders may include diarrhea and malabsorption from birth (congenital microvillus inclusion disease, tufting enteropathy, glucose-galactose transport defect, congenital chloride diarrhea, congenital bile acid malabsorption, congenital enterokinase deficiency). Alternatively, the symptoms may not present until the introduction of a new food (gluten in gluten-sensitive enteropathy, sucrose in congenital sucrase-isomaltase deficiency, lactose in congenital lactase deficiency). A careful history of the time of onset of symptoms and the relation to diet is helpful. Often, well-intended parents may assume that symptoms are

TABLE 320.1-1 -- Generalized Malabsorptive States in Childhood

Site	More Common	Less Common
Exocrine pancreas	Cystic fibrosis	Shwachman-Diamond syndrome
	Chronic protein-calorie malnutrition	Chronic pancreatitis Pearson syndrome
Liver, biliary tree	Biliary atresia	Other cholestatic states (including Alagille syndrome, familial neonatal hepatitis)
Intestine		
Anatomic defects	Massive resection Stagnant loop syndrome	Congenitally short gut
Chronic infection	Giardiasis	Immune deficiency
Others	Celiac disease	Tropical sprue
	Dietary protein intolerance (milk, soy)	Idiopathic diffuse mucosal lesions

associated with events that may, in fact, be coincidental. If a dietary component is important in the cause of the malabsorption, repetition of symptoms should occur on re-introduction of the substance and improvement should be reproducibly associated with removal of the offending agent. Frequency, looseness, and quantity of stool can be helpful in formulating a differential diagnosis; however, color, other than the pale stool of fat malabsorption, typically does not provide a clue. Failure to thrive can be caused by many systemic or psychosocial disorders, and one must keep this possibility in mind before making a diagnosis of malabsorption. A common example is the child with chronic, nonspecific diarrhea (toddler's diarrhea) who may unadvisedly receive frequent periods of a clear-liquid diet and may lose weight as a result. These children can appear on examination to have a malabsorption syndrome

such as gluten-sensitive

Figure 320.1-1 An 18-mo-old boy with active celiac disease. Note the loose skinfolds, marked proximal muscle wasting, and full abdomen. The child looks ill.

TABLE 320.1-2 -- **Specific Defects of Digestive-Absorptive Function in Children**

Variable	Disease
Intestinal	
Fat	Abetalipoproteinemia
Protein	Enterokinase deficiency
	Amino acid transport defects (cystinuria, Hartnup disease, methionine malabsorption, blue diaper syndrome)
Carbohydrate	Disaccharidase deficiencies (congenital: sucraseisomaltase, lactase; developmental: lactase, acquired)
	Glucose-galactose malabsorption (congenital, acquired)
	Glucoamylase deficiency (starch malabsorption)
Vitamin	Vitamin B_{12} malabsorption (juvenile pernicious anemia, transcobalamin II deficiency, Imerslund syndrome)
	Folic acid malabsorption
Ions, trace elements	Chloride-losing diarrhea
	Congenital sodium diarrhea
	Acrodermatitis enteropathica (zinc)
	Menkes syndrome (copper)
	Vitamin D–dependent rickets
	Primary hypomagnesemia
Drug-induced	
	Sulfasalazine (folic acid malabsorption)
	Cholestyramine (calcium, fat malabsorption)
	Phenytoin (calcium malabsorption)
Pancreatic	
	Specific enzyme deficiencies
	Lipase
	Trypsinogen

enteropathy. They typically respond to a return to a regular diet with improved weight gain.

The usual growth pattern associated with malabsorption and malnutrition demonstrates an initial decrease in weight followed by a deceleration in height velocity (Fig. 320–2). To make this assessment, it is essential to obtain serial weights and heights. The head circumference is usually normal, and growth of the head will be compromised when malnutrition becomes chronic. Signs of malnutrition may include lethargy, decreased subcutaneous tissue, muscle wasting, edema, clubbing, depigmentation of skin and hair, hemorrhagic diathesis, eczema, and follicular hyperkeratosis. Patients may also present with cheilosis, stomatitis, glossitis, and diffuse abdominal pain.

Initially, many infants with fat malabsorption have a voracious appetite. Other offending foods may produce avoidance behaviors if malabsorption produces gaseous distention (carbohydrates); gluten enteropathy frequently produces anorexia. The examination is typically not helpful in making a specific diagnosis, although occasionally features such as digital clubbing (cystic fibrosis, gluten-sensitive enteropathy), severe growth retardation of Shwachman syndrome, or the facial features of the Johannson-Blizzard syndrome can be helpful. A carotenemic infant or toddler is unlikely to have fat malabsorption.

Laboratory Findings.

The most useful screening test for malabsorption is a microscopic examination of stool for fat. This test can be performed by mixing a small amount of stool with several drops of water or Sudan red stain. Fat droplets separate and can be easily identified, especially with a Sudan III stain. The presence of more than six to eight droplets per low-power field is abnormal. Droplets tend to accumulate at the edges of the coverslip. The addition of acetic acid is thought to protonate ionized fatty acids

and to increase the number of droplets identified with Sudan stain. Castor oil, mineral oil, physiologic low levels of pancreatic enzymes in the neonate, extremely high fiber diets, and consumption of the nonabsorbable dietary additive Olestra can give a false-positive result. False-negative results may be seen with inadequate dietary fat intake. A positive test

Figure 320.1-2 Gluten-sensitive enteropathy. Growth curve demonstrates initial normal growth from 0–9 mo, followed by onset of poor appetite with intermittent vomiting and diarrhea after initiation of gluten-containing diet (*single arrow*). After biopsy-confirmed diagnosis and treatment with gluten-free diet (*double arrow*), growth improves.

should be confirmed with a 72-hr quantitative fecal fat test, which remains the gold standard for assessing steatorrhea. Excretion of more than 7% of the total fat intake is abnormal and suggests the presence of malabsorption. Fecal fat concentration lacks the sensitivity and specificity to differentiate between the different causes of fat malabsorption. False-negative and false-positive results may occur under the same circumstances as with the use of the Sudan stain.

A dietary record during this period is used to calculate the fat intake. Many clinicians use the diet history as an average 3-day intake and collect stools from the beginning to the end of this period. Fat absorption is calculated by subtracting fat excretion from intake and dividing by fat intake; this fraction is multiplied by 100 to give the percentage of intake that is assimilated, known as the *coefficient of fat absorption.*

The ability to assimilate dietary fat varies with the maturity of the infant and the type of fat offered in the diet. A premature infant may absorb only 65–75% of dietary fat, whereas a full-term infant absorbs 90%. Therefore, the finding of fat in the stool on microscopic examination in young infants is not necessarily abnormal. Older children and adults should absorb at least 95% of the fat in a typical diet. Butterfat is absorbed less well than vegetable fat, although human milk fat is absorbed best of all. The mild decreased ability to assimilate fat by infants reflects a decrease in pancreatic enzyme secretion or a decrease in duodenal bile acid levels. In disorders with pancreatic insufficiency (cystic fibrosis or Shwachman syndrome), the fat droplets number in the hundreds to thousands. Some malabsorption syndromes, such as gluten-sensitive enteropathy, may not always be associated with fat in the stool. Serum carotene levels have also been used as a screening test for fat malabsorption, but false-negative and false-positive results are common. The child must be receiving carotene in the diet for the test to be valid.

Steatorrhea is most prominent in disorders associated with pancreatic insufficiency; this finding warrants a sweat chloride test for cystic fibrosis as one of the initial studies. Three categories of exocrine pancreatic tests have been described: direct, indirect, and blood tests. The *direct tests* (secretin, cholecystokinin stimulation tests) assess the secretory capacity of the exocrine pancreas. The *indirect tests* detect abnormalities secondary to a loss of pancreatic function. These tests depend on the ability of the pancreatic secretagogue to break down substrate, which will provide an end product that could be recovered in the breath (carbon-13 lipids), serum and urine (bentiromide test, pancreolauryl), or stools (72-hr fecal fat, stool spot fat, trypsin chymotrypsin, elastase). The fecal elastase 1 is also useful. An enzyme-linked immunosorbent assay (ELISA) assesses elastase 1 as an indirect method of pancreatic function. Elastase 1 is an endoprotease, and it is both a human and pancreas specific protein. It is stable during conditions of abnormal intestinal transport, and it is not altered by supplementation of pancreatic enzymes. It is more sensitive than fecal chymotrypsin and will remain viable after up to 1 wk at room temperature. Its storability and the absolute specificity make this test a very attractive option to assess pancreatic function. *Blood tests* will detect pancreatic enzymes and hormones that are synthesized by the pancreas and which are normally found in the serum (trypsinogen). Measurement of serum levels of trypsinogen has proven to be a good screening test for pancreatic insufficiency in that it reflects residual exocrine pancreatic function. In cystic fibrosis with pancreatic insufficiency, the level is greatly elevated early in life but then falls, so that by 5–7 yr of age most patients have subnormal values. The levels in children with cystic fibrosis and pancreatic sufficiency are more variable but tend to be normal or elevated. In such children the trend over time is more helpful than a single value in monitoring pancreatic function. In Shwachman syndrome the serum trypsinogen level is low. The gold standard for determining pancreatic function resides in the ability to analyze duodenal contents after administration of a direct test, most commonly secretin and cholecystokinin stimulation tests. The procedure is cumbersome and involves intubation of the duodenum to aspirate its contents and avoiding direct contact with the stomach acid secretions. Few centers in the United States perform this analysis with reliable results. All the available tests to assess pancreatic function have at least one drawback.

Other initial studies should include a complete blood cell count, serum albumin determination, and measurement of serum immunoglobulin levels. Many different gastrointestinal disorders can cause hypoproteinemia as a result of decreased ability to assimilate dietary protein, inadequate protein intake, or protein-losing enteropathy (Box 320–1).

Measurement of carbohydrate in the stool using the Clinitest reagent for reducing substances is a simple screening test and can be performed at the bedside. The test is easily performed by combining 10 drops of water with 5 drops of stool and then adding a Clinitest tablet. The color change can be quantified as trace to 4+ using a color sheet provided by the manufacturer. Only 2+ or higher should raise the possibility of sugar malabsorption. Sucrose is not a reducing sugar and requires hydrolysis with hydrochloric acid before analysis.

If carbohydrates are not digested and absorbed in the small bowel, when they reach the colon they undergo degradation, where the final products are lactic acid and short-chain fatty acids such as butyrate, acetate, and propionate. There is production of methane, carbon dioxide, and hydrogen gases. Excess of carbohydrate spillage in the colon will lead to acidic stools and flatulence, which potentially could cause abdominal distention, discomfort, and a perineal chemical burn. Stool pH, obtained

Box 320.1-1. Gastrointestinal Causes of Hypoproteinemia

- Inflammatory bowel disease
- Gluten-sensitive enteropathy
- Cystic fibrosis
- Shwachman syndrome
- Disorders with secondary small-bowel mucosal damage (e.g., infectious disorders)
- Intestinal lymphangiectasia (primary or secondary)
- Hypertrophic gastropathy
- Eosinophilic gastroenteropathy
- Milk protein sensitivity
- Trypsinogen or enterokinase deficiency

easily with pH paper, lower than 5.6 is also suggestive of carbohydrate malabsorption. Osmotic diarrhea may be seen with carbohydrate malabsorption. Calculation of the “stool osmotic gap”: osmotic gap (mOsm/L) = 290 - 2 (Stool Na^+ + Stool K^+). A stool Na^+ level less than 70?mEq/L and an osmotic gap more than 100?mOsm/L suggest malabsorption from an excessive osmotic load (e.g., malabsorbed carbohydrate). The breath hydrogen test can also be used to evaluate carbohydrate malabsorption. The gas produced by bacterial degradation of carbohydrates is largely absorbed in the colon, enters the portal and systemic venous return, goes to the lung, and is then released in the breath. The child ingests a load of carbohydrate (1–2?g/kg, maximum 50?g), and the breath is collected in sealed plastic containers at timed intervals up to 2?hr after ingestion. The hydrogen content of the gas can be easily measured and is reported in parts per million (ppm). Malabsorption of any carbohydrate can be evaluated. The child should not be taking antibiotics at the time of the study because these drugs alter the colon flora and suppress hydrogen gas production. If a question exists about the ability of the colonic flora to produce hydrogen gas, the child can ingest the nonabsorbable disaccharide lactulose. A lack of hydrogen production with lactulose implies that the breath hydrogen test is not reliable in the child at that time. The major problem with the breath hydrogen study is that it is so sensitive that it identifies carbohydrate malabsorption that may not be clinically important (asymptomatic). A rise in hydrogen excretion of greater than 20?ppm from baseline is consistent with carbohydrate malabsorption.

Protein loss caused by maldigestion or malabsorption cannot be evaluated directly because bacterial protein accounts for such a large proportion of the stool nitrogen. Dietary protein is almost completely absorbed before reaching the terminal ileum. Endogenous intestinal proteins in the small bowel lumen are normally digested as well; less than 1?g of endogenous protein and products of digestion of exogenous protein pass into the colon. As a result, most of the colonic protein content is of bacterial origin.

A low serum albumin level may be the result of difficulty assimilating dietary protein, but it can also occur as a result of protein-losing enteropathy, inadequate protein intake, liver disease (reduced production), or renal disease. With protein-losing enteropathy, the peptide and amino acid products of digestion of the protein that enters the bowel lumen can be reabsorbed. Therefore, the child is not actually in negative nitrogen balance, even though levels of serum proteins including albumin and immunoglobulins are reduced.

Measurement of spot stool a_1 -antitrypsin levels is helpful in establishing a diagnosis of protein-losing enteropathy. This serum protein is resistant to digestion and therefore can be measured in stool in contrast to albumin. One- or 2-day collections of stool for a_1 -antitrypsin measurement or clearance studies are much more difficult to complete and do not appear to improve the test's reliability.

Nutrients that may be measured in blood include the following: iron, the level of which depends on transferrin concentration as well as on absorption; folic acid, the red cell concentration being a more accurate reflection of nutritional status than the serum concentration; calcium, zinc, and magnesium; vitamin D and its metabolites; vitamin A; and vitamin B_{12} . If the intake of these nutrients is adequate, decreased concentrations will suggest inadequate absorption. It may take years to deplete stores of vitamin B_{12} after absorption is impaired. Vitamin E levels should be measured simultaneously with serum lipid levels and the value expressed as a ratio to lipid concentration. Vitamin K stores can be assessed by measuring prothrombin (more sensitive) and partial thromboplastin times because these times will be prolonged if the vitamin K–dependent coagulation factors are depleted.

Certain absorptive studies help to localize an intestinal lesion. Iron and d-xylose, a pentose minimally metabolized in humans, are absorbed by the upper small bowel. A blood concentration of less than 25?mg/dL of xylose 1?hr after a 14.5?g/m^2 oral dose (maximum dose: 25?g) suggests a proximal intestinal mucosal lesion, but some false-negative and false-positive results are obtained using this technique. In the distal bowel, vitamin B_{12} is absorbed and bile salts are reabsorbed. *Vitamin B_{12}* absorption can be measured directly using the *Schilling test,* in which, after body stores of the vitamin are saturated, a tracer dose of radioactive vitamin B_{12} is given by mouth, with or without intrinsic factor, and urinary excretion is measured over the next 24?hr. Defective absorption in the presence of intrinsic factor, shown by urinary excretion of less than 5% of the dose, occurs when an extensive length of distal ileum is resected or diseased or when bacterial overgrowth occurs within the bowel lumen.

Diagnosis

MICROBIOLOGIC.

The only common primary infection causing chronic malabsorption is giardiasis (see Chapter 258 and Table 317–2). Techniques to fix and stain specimens have greatly improved the diagnostic value of examining stools for *Giardia* cysts. The trophozoite may be identified in fresh duodenal contents or the duodenal mucosa. Immunoassay techniques are also available to identify *Giardia* antigen in the stool and antibody in the serum. These tests appear sensitive and specific. When enteric clearing of bacteria is impaired, either from stasis of luminal contents or impaired immune function, colony counts from bacterial cultures of proximal intestinal juice may be very high.

Failure to thrive with chronic diarrhea may be the first sign of HIV infection (AIDS) (see Chapter 254) and congenital T- or B-cell defects. The cause may be primary infection or parasitic, bacterial, or viral opportunistic enteric pathogens.

SMALL BOWEL BIOPSY.

Small bowel biopsy identifies diseases of the small bowel mucosa that are associated with histologic findings, including gluten-sensitive enteropathy, abetalipoproteinemia, lymphangiectasia, congenital microvillus inclusion disease, eosinophilic gastroenteritis, infectious disorders, and Whipple disease (rare in children). The biopsy can be safely performed by upper gastrointestinal endoscopy. At the time of biopsy, in addition to mucosa, it is possible to collect aspirates for examination for *Giardia* or bacterial culture. Mucosal samples can be frozen to assay for disaccharidase activities later. Depression of activities of all enzymes tested suggests a secondary deficiency associated with mucosal damage. Reduction of a specific enzyme or group of enzymes is consistent with a specific deficiency (lactase or sucrase-isomaltase deficiency).

HEMATOLOGIC.

A hypochromic, microcytic blood smear indicates iron deficiency; a macrocytic smear suggests deficiency and therefore malabsorption of folic acid or vitamin B_{12} . Acanthocyte transformation of erythrocytes occurs in abetalipoproteinemia. A blood smear may also suggest a lymphocyte defect or neutropenia associated with Shwachman-Diamond syndrome.

IMAGING PROCEDURES.

Used primarily to identify local lesions in the abdomen, these procedures have limited application to the study of children with malabsorptive disorders. *Plain radiographs* and *barium contrast studies* may suggest a site and cause of intestinal stasis. The most common anomaly causing incomplete bowel obstruction is intestinal malrotation, which can be diagnosed with barium contrast studies. Although flocculation of normal barium and dilated bowel with thickened mucosal folds have been attributed to diffuse malabsorptive lesions such as celiac disease, these abnormalities are nonspecific. The presence of multiple ulcerations in the duodenum with proximal small bowel edema suggests Zollinger-Ellison syndrome, a rare cause of malabsorption in children. *Ultrasound* can detect alterations in pancreatic mass, biliary tree abnormalities, and stones. *Retrograde studies* of the *pancreatic* and *biliary tree* using contrast medium injection by means of endoscopy are reserved for rare cases requiring careful delineation of the biliary and pancreatic ducts.

320.2 Chronic Malnutrition

Chronic protein-calorie malnutrition can lead to compromise of pancreatic and small bowel function. In developed countries, primary malnutrition is rare and chronic digestive disorders account for many cases of malnutrition in children. Environmental deprivation is also an important cause, as are feeding disorders (improper volume or dilution of formula). Protein-calorie malnutrition appears to contribute to the cycle of protracted diarrhea of infancy, perhaps through impairment of the functional capacity of the bowel, impairment of immune function, or the development of small bowel bacterial overgrowth. Worldwide, exocrine pancreatic insufficiency is most often attributable to malnutrition, not to a primary pancreatic disease.

The intestine is remarkably resistant to the effects of protein-calorie malnutrition. Patients with *kwashiorkor* may have a severely flattened small intestinal villi (see Chapter 42); these abnormalities are probably attributable to coexisting infections and infestations. In *marasmus,* villus structure is relatively well preserved, although microvillus changes and intracellular electron microscopic abnormalities are observed (see Chapter 42). Chronic malnutrition can lead to impaired immune function; bacterial overgrowth of the upper intestine is seen in malnourished subjects (see Chapter 42). When oral intake is withheld in experimental animals, intestinal mucosal mass and absorptive function diminish even if nutrient is supplied by the intravenous route. These changes can be reversed by small amounts of oral nutrient. Accordingly, a theoretical advantage exists in delivering nutrients via the gut. Recovery from injury to the gastrointestinal tract (viral gastroenteritis) may be prolonged by chronic malnutrition. Certain nutrients, such as glutamine, soluble fiber, short-chain fatty acids, and short-chain triglycerides, may promote small bowel mucosal growth.

Little is known about the *effect of specific nutritional deficiencies* on the pancreas or intestine; apart from potassium depletion causing ileus and severe dehydration causing constipation, available data suggest a relatively minor clinical effect of a wide range of specific deficiencies. Iron deficiency is associated with enhanced iron uptake at the mucosa and, in a few severe cases, occurrence of mucosal flattening. Deficiencies of vitamin B_{12} and folic acid may cause distortion of enterocyte morphology but no known serious functional abnormalities of the gut. Some hypocalcemic states may be accompanied by steatorrhea and even by ion and water secretion, but this poorly understood relationship is not constant.

Vitamin A supplementation reduces childhood mortality in developing countries. Improved survival during measles and a reduction in relative risk of contracting diarrheal and respiratory diseases have been identified. The explanation for this finding is uncertain, but children with vitamin A deficiency may have T-cell defects

(including a low CD4:CD8 ratio), which can be reversed with vitamin supplementation.

320.3 Liver and Biliary Disorders

Cholestatic liver disease and biliary disorders may lead to fat malabsorption by reducing the duodenal bile acid concentration to less than the critical micellar concentration. In addition to steatorrhea, patients with these disorders have a propensity to acquire deficiencies of fat-soluble vitamins (vitamins A, D, E, and K). These deficiencies have no consistent pattern, except vitamin A is least likely to be problematic.

Vitamin E deficiency in patients with chronic cholestasis has been associated with a progressive neurologic syndrome, which includes peripheral neuropathy (presenting as loss of deep tendon reflexes and ophthalmoplegia), cerebellar ataxia, and posterior column dysfunction. Early in the course findings are partially reversible with treatment; late features may not be reversible. It can be difficult to identify vitamin E deficiency because the elevated blood lipid levels of cholestasis can falsely elevate the serum level of vitamin E. Therefore, it is important to measure the ratio of serum vitamin E to total serum lipids if one suspects this deficiency; the normal level for patients younger than 12 yr is greater than 0.6 and for patients 12 yr and older, greater than 0.8. The neurologic disease can be prevented with the use of an oral water-soluble vitamin E preparation (*d*-a-tocopherol polyethylene glycol-1,000 succinate [TPGS], Liqui-E) at 25–50?IU/24?hr in neonates and 1?IU/kg/24?hr in children.

Metabolic bone disease can develop secondary to vitamin D deficiency. Simultaneous administration of vitamin D with the water-soluble vitamin E preparation (TPGS) enhances absorption of vitamin D. In young infants, oral vitamin D_3 is given at 1,000?IU/kg/24?hr. After 1 mo, if the serum 25-hydroxyvitamin D level is low, the same dose of oral vitamin D is mixed with TPGS. 25-Hydroxyvitamin D is then monitored every 3 mo, with adjustment of doses as necessary.

Vitamin K deficiency can occur as a result of cholestasis and poor fat absorption. Easy bleeding may be the first sign, or a child may be identified before symptoms develop through routine screening of prothrombin (a more sensitive test) and partial thromboplastin times. It is possible for a patient taking the standard oral preparation to acquire vitamin K–deficient coagulopathy because the currently available oral preparation of vitamin K is not well absorbed.

320.4 Intestinal Infections

Malabsorption is a rare consequence of primary intestinal infection in immunocompetent children. Giardiasis is the most common infectious cause of chronic malabsorption (see Chapter 258). Factors that regulate the range of host response to *Giardia* (asymptomatic, acute, or chronic infection) remain to be explained. Symptoms may include diarrhea, vomiting, bloating, and gas. Giardiasis should be suspected if a child with persistent acquired malabsorption has family members who have had transient gastroenteritis symptoms at the onset of the child's illness. Children in daycare (especially toddlers) are at special risk for *Giardia,* although they may be asymptomatic and may pass it on to family members. Other common microorganisms that can lead to intestinal mucosal lesions and, hence, malabsorption are rotavirus, *Campylobacter, Shigella,* and *Salmonella.* Cryptosporidiosis can also occur in immunocompetent persons, as can coccidioidosis. Infectious causes of malabsorption are especially common in immunocompromised persons (see Chapter 164 , Chapter 317 , and Chapter 320.5).

320.5 Immunodeficiency

Gastrointestinal symptoms are a common manifestation of many immune deficiency states, including AIDS, congenital neutrophil and T- and B-cell immune deficiencies, and conditions of medical immune suppression (cancer and transplantation therapy). Most children with AIDS have diarrhea at some time. The more common congenital disorders associated with bowel disease include severe combined immunodeficiency, agammaglobulinemia, Wiskott-Aldrich syndrome, common variable immunodeficiency disease, and chronic granulomatous disease. Gastrointestinal symptoms of congenital X-linked hypogammaglobulinemia tend to be milder (chronic rotavirus or enterovirus infection or giardiasis). Malabsorption occurs in about 10% of patients with late-onset common variable hypogammaglobulinemia, a primary disorder that presents later in life. Nodular lymphoid hyperplasia may be noted on small bowel radiographs. T-cell abnormalities can also be associated with malabsorption. Selective immunoglobulin (Ig) A deficiency is common and may not always be associated with gastrointestinal symptoms, but it may be associated with an increased incidence of gluten-sensitive enteropathy, nodular lymphoid hyperplasia, inflammatory bowel disease, and giardiasis.

Chronic giardiasis and rotavirus infection have been noted to cause malabsorption in children with immune deficiencies. Small bowel bacterial overgrowth and infections with *Yersinia* and *Campylobacter* are seen in immunodeficient patients, leading to chronic diarrhea and malabsorption.

In addition, in children with AIDS, other organisms, including opportunistic infections, that can interfere with bowel function include *Cryptosporidium parvum*, cytomegalovirus, *Mycobacterium avium-intracellulare, Isospora belli, Enterocytozoon bieneusi, Candida albicans,* astrovirus, calicivirus, adenovirus, and the usual bacterial enteropathogens. Likelihood of infection is related to the CD4 count. *Cryptosporidium* can cause chronic secretory diarrhea and can be carried chronically in the gallbladder. HIV itself appears to be a primary bowel pathogen. Disaccharide intolerance is common in HIV-infected children but does not correlate well with enteric infection. Pancreatic insufficiency with steatorrhea and vitamin B_{12} malabsorption have been described to occur in patients with AIDS. Malnutrition and failure to thrive occur in the majority of untreated children with AIDS; diarrhea is common, although frequently pathogens are not identified. In addition to the range of infectious causes in immunosuppressed children, diarrhea can be a presentation of toxicity to the drug tacrolimus or of immunosuppression-induced lymphoproliferative disease.

Deficiency of neutrophils, congenital cyclic neutropenia, or, more commonly, the neutropenia associated with cancer chemotherapy predisposes children to neutropenic enterocolitis. The colitis can be manifested as mild bloody diarrhea, or it may present as fever, severe right lower quadrant pain, bloody stools, and diarrhea. The latter disorder, known as typhlitis, occurs most often in the lower ileum, cecum, and proximal colon, where vascular compromise, mucosal ulceration, and perforation carry a high mortality. Children with neutropenia are also at risk for fungal infections of the gastrointestinal tract including infections with *Histoplasma, Aspergillus,* and *Mucor.* Enterocolitis may be caused by *Clostridium difficile* in children receiving chemotherapy or long-term antibiotic therapy. In patients with chronic granulomatous disease, phagocytic function is impaired and granulomas may develop throughout the intestine, thus causing diarrhea and malabsorption and mimicking Crohn disease. Inflammation with granulomas, characterized by giant cells and lipid-containing histiocytes, may obstruct the gastric antrum. Children with chronic granulomatous disease are at risk for *Salmonella* infections as well.

320.6 Stagnant Loop Syndrome (Blind Loop Syndrome: Bacterial Overgrowth Syndrome)

These syndromes are characterized by an abnormally high bacterial population in the small bowel, exceeding 10^5 organisms/mL; they are associated with stasis of small intestinal contents, particularly in the upper regions. Incomplete bowel obstruction, either congenital (malrotation with duodenal bands, stenosis, intestinal duplications, duodenal webs, or a diverticulum) or acquired (postoperative intestinal adhesions, long-standing Crohn disease), impairs intestinal motility or causes loss of the normal intestinal mucosal barrier to microorganisms, allowing enteric bacteria to colonize the upper small bowel. Primary dysmotility disorders of the gastrointestinal tract, such as intestinal pseudo-obstruction and systemic disorders like diabetes mellitus, and scleroderma could result in bacterial overgrowth. Prematurity, immunodeficiency, and malnutrition are other factors that could lead to bacterial overpopulation of the small bowel. Bacteria deconjugate bile salts, a process that leads to inefficient intraluminal processing of dietary fat and to steatorrhea; they bind vitamin B_{12} , interfering with its absorption; and they may damage the microvillus brush border membrane, diminishing disaccharidase activities.

In addition to symptoms of chronic incomplete bowel obstruction such as distention, pain, and vomiting, the patient may have pale, foul-smelling, bulky stools typical of steatorrhea, megaloblastic anemia from vitamin B_{12} deficiency, or diarrhea from disaccharidase deficiency. Clinical manifestations often do not suggest chronic intestinal obstruction, but laboratory investigations find the aforementioned functional abnormalities as well as bacterial colonization of the upper intestine and deconjugated bile salts in the upper intestinal juice after a fatty meal. Barium contrast radiographs may reveal neither the existence nor the cause of obstruction.

Oral administration of antibiotics may be sufficient to control the problem temporarily. Metronidazole has been used for the treatment of bacterial overgrowth. An initial course of 2–4 wk may give relief for many months. If there is a relapse of symptoms, a longer treatment period (4–8 wk) is recommended. At times, cycling of antibiotics may be effective for a longer period of management. Other alternatives are oral nonabsorbable antibiotics for gram-negative bacteria (gentamicin, colistin) and trimethoprim-sulfamethoxazole. In older teenagers, tetracycline or ciprofloxacin may be used. Operative correction of a persistent partial small bowel obstruction is the ideal approach.

320.7 Short Bowel Syndrome

Short bowel syndrome produces malabsorption and malnutrition after congenital or postnatal loss of at least 50% of the small bowel, with or without loss of a portion of the large intestine. Traditional teaching is that the presence of a functioning ileocecal valve appears to have a prognostic value in short bowel syndrome. An infant with as little as 15?cm of bowel with an ileocecal valve, or 20?cm without, has the potential to survive and eventually to be weaned from total parenteral nutrition (TPN). These numbers are only applicable to the patients who had their resection as neonates. Older children can also adapt in spite of significant intestinal resection. The advances in TPN and better understanding of this condition have made predicting outcomes more difficult.

Short bowel results in inadequate absorptive surface and compromised bowel function. The condition may not be permanent because the intestine has the capacity for adaptive growth and increase in functional capacity. Adaptation is a gradual process associated with increase in villus height and small bowel surface, rather than lengthening of the bowel.

The small intestine may be congenitally short in conditions in which bowel is lost in utero (malrotation, gastroschisis, and, in some cases, atresia). Multiple atresias may be the result of anomalies in the superior mesenteric artery, and these produce an “apple peel” deformity of the small bowel. Most cases involve some surgical resection of the small intestine. Most occur in the neonatal period (necrotizing enterocolitis), although Crohn disease or trauma can account for later onset.

Clinical Manifestations.

The major clinical manifestations are malabsorption and diarrhea. The ability to assimilate nutrients correlates with the length and location as well as the quality of the residual bowel. Carbohydrate malabsorption and steatorrhea are common features resulting in diarrhea and failure to thrive. Large volumes of fluid and electrolyte are normally secreted into the upper gastrointestinal tract and must be reabsorbed. The capacity to reabsorb fluid and electrolyte is usually inadequate in the short bowel syndrome and results in loss from the gastrointestinal tract with the potential for dehydration, hyponatremia, hypokalemia, and acidosis. The extent of loss is influenced by the presence or absence of the colon in continuity with the small bowel. Trace elements are also poorly absorbed and are lost in excess. D-Lactic acidosis may occur rarely as a result of fermentation of dietary carbohydrate by luminal bacteria in the small bowel caused by bacterial overgrowth. Patients with this manifestation experience confusion, hyperventilation, and acidosis with an anion gap in the absence of elevated serum lactate as measured by standard techniques, which measure L-lactate. Rapid enantiomeric differentiation of urinary metabolites can help diagnose D-lactic acidosis. Routine qualitative urinary organic acid analysis may

reveal increased excretion of lactate, 3-hydroxypropionate, phenylacetate, and 4-hydroxyphenylacetate, which is a urinary pattern, found in bacterial overgrowth syndrome. Hypersecretion of acid in the stomach occurs as a result of hypergastrinemia for a transient period after small bowel resection. However, this condition does not appear to cause problems in infants and children. These patients often have associated cholestasis resulting from hyperalimentation and other factors. Cholestasis may contribute to ongoing malabsorption of fat and fat-soluble vitamins and lead to cirrhosis.

Treatment.

More than 90% survive. The use of parenteral nutrition dramatically improves the outcome. These infants cannot maintain adequate nutrition by the enteral route alone and initially must have most of their nutrition given intravenously. Very small amounts of enteral nutrients are given at first as a continuous gastric infusion (1–5?mL/hr depending on the size of the infant). Usually an elemental diet is used at regular strength (20?kcal/oz). Exposure to enteral nutrients contributes to adaptive growth of the small bowel. As tolerated, the quantity can be slowly advanced, perhaps by 1–2?mL/hr/24?hr, as the amount of parenteral nutrition is simultaneously decreased. A level is reached at which diarrhea and malabsorption increase, and progression of enteral feedings must be delayed. Although the residual small bowel length remains an important predictor of duration of TPN, other factors such as the early introduction of maternal breast milk or amino acid–based formula are important in intestinal adaptation. The use of breast milk has correlated with shorter use of TPN. Breast milk contains high levels of IgA, nucleotides, and leukocytes that may enhance the protective mechanisms of the bowel. Other beneficial components of breast milk include long-chain fats, epidermal growth factor, growth hormone, glutamine, and free amino acids.

Bloody diarrhea secondary to patchy, mild colitis may develop during the progression of enteral feedings. The pathogenesis of this “feeding colitis” is unknown, but it is usually benign. It may respond to a hypoallergenic diet or to sulfasalazine. Strictures after neonatal necrotizing enterocolitis may also produce bloody stools (see Chapter 91.2).

When possible, an infant may be given a small amount of formula by mouth to maintain an interest in oral feeding and minimize or avoid the development of oral aversions. As children age beyond the 1st year, it is sometimes possible to add a small amount of solids by mouth (cereal, pureed chicken). For infants with an extremely short bowel, it may take several years or more until parenteral nutrition can be stopped.

Certain factors appear to influence the length of time until a child is independent of parenteral nutrition. Infants with less than 40?cm of small bowel take twice as long as infants with 40–80?cm of bowel (average of slightly more than 2 yr versus slightly more than 1 yr). The absence of an ileocecal valve doubles the time to complete adaptation, all other factors being equal. The length of residual ileum is inversely correlated with the time until adaptation. The presence of the ileocecal valve is not always associated with better outcome than is the absence of the valve. A better outcome is associated with breast milk, amino acid–based formula, percentage of kilocalories taken enterally by 6 wk of life, and residual small bowel length at the time of surgery. Identification of small bowel bacterial overgrowth has been associated with prolonged dependence on parenteral nutrition.

Bacterial overgrowth is common in infants with a short bowel and may delay progression of enteral feedings (see Chapter 320.6). Metronidazole is used empirically, as are nonabsorbable antibiotics that cover anaerobic and gram-negative bacteria. Occasionally, a drug that slows gastrointestinal motility, such as loperamide, can be helpful. However, these drugs often do not appear to alter the course. When the small bowel is in continuity with the colon, bile acid malabsorption can cause colonic fluid secretion. In this situation, cholestyramine, 0.25–1?g every 6–8?hr, may be helpful in reducing the watery diarrhea.

Long-Term Complications.

Long-term complications include those of parenteral nutrition: central catheter infection, thrombosis, hepatotoxicity, and gallstones. For this reason, a continual effort to advance enteral feedings slowly but aggressively must be considered. Enteral nutrition, even in small amounts, is extremely important in not only promoting intestinal adaptation but also preventing or minimizing the numerous complications associated with long-term TPN. Other long-term complications of short bowel include the potential for late vitamin B_{12} deficiency. Stores of vitamin B_{12} acquired in utero are so great that deficiency may not appear until 1–2 yr of age. Therefore, it is important to periodically check vitamin B_{12} levels during and after the 1st yr of life. Gallstones are found in 60% of infants receiving chronic parenteral nutrition who had had terminal ileal resection but in none of the children with an intact ileum. Renal stones can occur as a result of hyperoxaluria secondary to steatorrhea (calcium binds to the excess fat instead of to oxalate so more oxalate is reabsorbed and excreted in urine). Venous thrombosis and vitamin deficiency have been associated with hyperhomocystinemia in short bowel syndrome.

Future Directions in Management.

Certain nutrients have been considered potential stimulants of adaptive growth in experimental animals, but their role in humans remains to be determined. These include glutamine, soluble fiber, short-chain fatty acids, and short-chain triglycerides. Another area of interest is the role of peptide growth factors in promoting adaptive growth of the bowel. Bowel-lengthening surgical procedures have been performed with mixed results. A select group of children with intestinal failure, dependent on TPN, will develop life-threatening complications that would warrant intestinal transplantation. These complications are parenteral nutrition associated liver disease, recurrent events of septicemia, and loss of central vein access. Children with liver dysfunction should be considered for isolated intestinal transplant before terminal damage to the liver occurs. Combined small bowel and liver transplantation can be

performed and is a particular consideration for the child with severe TPN hepatotoxicity.

320.8 Gluten-Sensitive Enteropathy (Celiac Disease, Celiac Sprue)

Celiac disease is a disorder in which the proximal small bowel mucosa is damaged as a result of dietary exposure to gluten. It mostly affects people of northern Europe and their descendants in other parts of the world. It is not exclusive in whites because it has been also documented in Hispanics, Indians, Sudanese, Chinese, Afro-Caribbean, and Middle Eastern people. The disorder does not present until gluten products have been introduced into the diet. The most common period of presentation is between 6 mo and 2 yr of age, and it is a permanent intolerance to gluten. Prevalence varies in different regions of the world. The average incidence of celiac disease in Europe is 1 case in every 1,000 live births with a range of 1:250 in Sweden to 1:4,000 in Denmark. In the United Kingdom, the use of serologic screening, followed by diagnostic confirmation with a small bowel biopsy, showed a prevalence of 1:300. In Ireland the prevalence is higher than previously recognized, 1:150. Screening of 2,000 blood donors in the United States found a prevalence of elevated antiendomysial antibodies of 1:250. In Sweden, serologic screening test of a healthy pediatric population 2.5 yr of age, living in a suburban population with high incidence of celiac disease, showed a prevalence of at least 1% and may be as high as 2% counting "silent" celiac disease. These findings suggest that celiac disease may be one of the most common chronic disorders.

Pathogenesis.

The disorder develops only after long-term dietary exposure to the protein gluten, which is found in wheat, rye, and barley. The activity of gluten resides in the gliadin fraction, which contains certain repetitious amino acid sequences (motifs) that lead to sensitization of lamina propria lymphocytes. There is a genetic predisposition, as suggested by concordance in monozygotic twins approaching 100%. Two to 5% of 1st-degree relatives have symptomatic gluten-sensitive enteropathy, and as many as 10% of first-degree relatives have asymptomatic damage to small bowel mucosa consistent with this disorder. The disorder is associated with major histocompatibility complex class II alleles DQA1*0501 and DQB1*0201. This HLA-DQ2 allelic combination is found in 98% of celiac patients in Northern Europe. In Southern Europe, DQ2 is present in 92% of confirmed celiac disease patients. Celiac disease is associated with certain human leukocyte antigen (HLA) types (B8, DR7, DR3, and DQw2). Even though not all monozygotic twins have 100% concordance, those who are followed develop the disease at a later age. Other genetic influences, not linked to HLA, may be required for the development of the disease given that the rate of discordance in HLA-identical siblings is reported to be 30–50% and the risk in 1st-degree relatives is between 10–20%. It is estimated that around 25% of the normal Northern European population carries DQ2. Environmental factors may also play a role in the expression of this genetic predisposition.

The immunologic response involves the activation of a Th1/Th0 type of inflammatory response by CD4+ gluten-sensitive T cells. The inflammatory response results in villus atrophy, crypt hyperplasia, and damage to the surface epithelium in the small bowel. The injury is greatest in the proximal small bowel and extends distally for a variable distance. The latter observation is undoubtedly the explanation for the variable degree of symptoms and findings of malabsorption among persons with gluten-sensitive enteropathy. Large-scale screening studies in the adult population suggest that the diagnosed celiac population may represent a small fraction of a bigger problem, the undiagnosed population. The "asymptomatic" form of the disease, with typical serologic markers and histologic findings, may be five to seven times more common than the symptomatic disease. Four categories have been described for the undiagnosed population: (1) *undiagnosed celiac sprue* (these patients have the classic mucosal lesions and clinical symptoms but are undiagnosed); (2) *silent celiac sprue* (small bowel biopsy have characteristic findings but there is absence of clinical symptoms); (3) *latent celiac sprue* (there is genetic susceptibility but patients do not manifest histologic or clinical signs of the disease); and (4) *true normals* (lack genetic susceptibility and show no symptoms or signs of the disease). The intestinal lesion end product results in a decrease in the absorptive and digestive capacity of the small intestinal surface area and a relative increase in immature epithelial cells. Pancreatic secretion is decreased as a result of lowered serum cholecystokinin and secretin levels.

A 33-mer peptide has been identified that may be the primary initiation of the inflammatory response in susceptible individuals. It reacts with transglutaminase and is a potent inducer of gut derived human T-cell lines. If this peptide can be detoxified, an additional therapy may be developed.

Clinical Manifestations.

The mode of presentation is variable; most patients present with diarrhea (Table 320–3). Children can have failure to thrive or vomiting as the only manifestation. Perhaps as many as 10% of children referred to endocrinologists for growth retardation without an endocrine or overt gastrointestinal disorder have gluten sensitivity. Anorexia is common and may be the major cause of weight loss or lack of weight gain (see Fig. 320–2). Infants with gluten-sensitive enteropathy are often clingy, irritable, unhappy children who are difficult to comfort. In contrast to infants with cystic fibrosis, they are not interested in food, although this is not always the case. Pallor and abdominal distention are common (see Fig. 320–1). Large, bulky stools suggestive of constipation have been described in some children with this condition. Digital clubbing can occur. An increased prevalence of gluten-sensitive enteropathy has been noted in children with selective IgA deficiency, diabetes mellitus, chronic rheumatoid arthritis, thyroiditis, hypothyroidism, Addison disease, pernicious anemia, alopecia, and Down syndrome. Lymphocytic gastritis occurs in rare children with gluten-sensitive enteropathy. Pancreatic insufficiency is present in about one third of children with newly diagnosed celiac disease, usually resolving within the first months of treatment. Isolated idiopathic transaminasemia without other hepatic or enteric symptoms may be a manifestation of occult celiac disease. Macroamylasemia associated with celiac disease

TABLE 320.8-3 -- **Active Childhood Celiac Disease: 42 Cases**

	No. of Patients
Symptoms	
Failure to thrive	36
Diarrhea	30
Irritability	30

Vomiting	24

Signs	
Height <25th percentile	30
Body weight <25th percentile	37
Wasted muscles	40
Abdominal distention	33
Edema	14
Finger clubbing	11

and autoimmune thyroiditis has been reported. Ataxia has been described as the most common neurologic manifestation of celiac disease. It is seen in the adult population and presents as gait and limb ataxia due to cerebellar involvement. The gastrointestinal manifestations are negligible, and these patients could fall in the category of latent celiac disease. The ataxia in these patients seems to be a clinical manifestation of an immunologic reaction, with some of these patients having resolution of symptoms after a gluten-free diet. It has been recommended that in patients who present with ataxia, the possibility of celiac disease should be considered. It has not been described in the pediatric population, but it should be considered as a possibility even in childhood. Microcephaly, developmental delay, and areflexia have been described in a 15-mo-old female with celiac disease whose symptoms resolved after a gluten-free diet. Seizures may occur as childhood partial epilepsy with occipital paroxysms. Dermatitis herpetiformis has been associated with celiac disease in that some degree of gluten-sensitive enteropathy is common to both conditions. It manifests as a maculopapular rash localized to the extremities, buttocks, face, neck, and trunk. Oral involvement has been described. It shares the constitutional and gastrointestinal symptoms found with celiac enteropathy. Almost 100% of these patients show patchy small bowel mucosal atrophy and inflammation.

Evaluation.

Screening tests for malabsorption are not particularly helpful because results may be normal in a child with gluten-sensitive enteropathy. Anemia and hypoproteinemia may be present. There may be a mild dimorphic anemia; the blood smear may show target cells, Howell-Jolly bodies, Heinz bodies, siderocytes, and irregular and crenated cells with signs of hyposplenism. Splenic atrophy occurs commonly in celiac sprue in the adult. The incidence of iron deficiency with microcytic anemia is variable. Although rare, a macrocytic megaloblastic anemia can occur. Hypoprothrombinemia can occur as a result of malabsorption. Serologic markers include antibodies to gliadin, reticulin, endomysium, and tissue transglutaminase (tTG). The antigliadin antibodies are in the form of IgG and IgA. The sensitivity of IgG and IgA antigliadin antibodies is believed to be 100% and 89%, respectively, in children with celiac disease. The specificity was 95.5% for IgA and 86% for IgG antigliadin antibodies. It is estimated that 2–3% of celiac disease patients are IgA deficient. Antigliadin antibodies can also be present in other conditions such as cow's milk protein enteropathy, Crohn disease, IgA nephropathy eosinophilic enteritis, tropical sprue, and dermatitis herpetiformis. Antiendomysial antibodies (EMAs) also belong to the family of the IgA antibodies. The sensitivity is reported to be nearly 100%, and the specificity is around 98%. The use of the antigliadin antibodies and antiendomysial antibody together in screening of celiac disease patients confers positive and negative predictive values of almost 100%. The antigen for antiendomysial antibody is tissue transglutaminase. An ELISA for both IgA and IgG tTG is an attractive screening test in that it has high specificity and sensitivity equivalent to the antiendomysial test, is easier to standardize, and does not require the use of human or animal tissue. The tTG IgA assay has a specificity of 95–98% and a sensitivity of 92–94%. Patients with celiac disease who are IgA deficient are positive for the IgG tTG ELISA. Tissue transglutaminase is also valuable in screening *asymptomatic* patients who have type 1 diabetes, history of a 1st-degree relative with type 1 diabetes, and a family member with celiac disease. It has a positive predictive value between 70–83% for biopsy evidence of celiac disease. This may identify children who are at risk of developing symptomatic celiac disease and allows early intervention.

The combination of clinical symptoms and serologic markers may suggest the diagnosis of celiac disease, but histologic confirmation is mandatory, because it remains the gold standard. In 1969, the European Society of Pediatric Gastroenterology and Nutrition (ESPGAN) recommended that the diagnosis be confirmed by showing that the small bowel biopsy returned to normal within 1–2 yr after starting a gluten-free diet and then to rechallenge the patient with a gluten diet and repeat the biopsy to demonstrate the return of the intestinal lesion. ESPGAN now recommends the following: For children older than 2 yr, it is not necessary to rechallenge if the gluten-free diet has produced resolution of symptoms and normalized the specific celiac disease serologies (EMAs, Ab to tTG). For children younger than 2 yr, and when the diagnosis is in question, a rechallenge is recommended. In this age group, other conditions can lead to a flattened small bowel mucosa.

Pathology.

The diffuse lesion of the upper small intestinal mucosa that characterizes celiac disease is seen on small bowel biopsy. Short, flat villi, deepened crypts, and irregular vacuolated surface epithelium with increased numbers of lymphocytes in the epithelial layer and crypt hyperplasia are seen by light microscopy. Similar abnormalities occur in other conditions, but none is likely to be confused with celiac disease. Infections such as rotavirus enteritis, *Giardia lamblia,* or tropical sprue can cause villus flattening and elongated crypts but not the marked abnormalities of enterocytes. Flat mucosa occurs in kwashiorkor but may represent a response to infestation rather than to undernutrition. Tropical sprue, a poorly understood tropical

enteropathy, can cause a lesion that is indistinguishable from that of celiac disease. Some cases of cow's milk protein or soy protein intolerance are associated with lesions similar to those of celiac disease in children. In immune deficiency, eosinophilic gastroenteritis, and autoimmune enteropathy, villi can be partially shortened. Infants with familial enteropathy have short villi, but the crypt dimensions are normal.

Treatment.

Treatment requires a lifelong, strict gluten-free diet. All wheat, rye, and barley products should be eliminated from the diet. Counseling from an experienced dietitian should be provided. There is disagreement about the toxicity of oats, and some physicians will allow oats in the diet of the child. A note of caution should be exercised since oats may be processed in the same mill where wheat is processed, leading to contamination. Initially, vitamin and iron supplementation is advisable. National celiac support groups provide much specific information about the gluten content of foods and medications. Processed foods must be considered carefully because they commonly contain some gluten. Gluten-free foods are commercially available. Poor weight gain in the first months after diagnosis may improve with pancreatic enzyme treatment.

Celiac disease can also present as severe diarrhea, weight loss, hypocalcemia, and hypoproteinemia, a condition known as a celiac crisis. Treatment of a celiac crisis is supportive and includes the use of corticosteroids. Osteopenia is a frequent complication of celiac disease, and it is usually reversed with a strict gluten-free diet.

Compliance with a strict gluten-free diet can be followed with the serologic markers. The antibodies will decrease to normal levels on a strict gluten-free diet. Small amounts of gluten in the diet, owing to less than optimal compliance, will result in elevation of tTG in serum.

Prognosis.

The clinical response to a gluten-free diet of a child with celiac disease is gratifying. Improvement of mood and appetite is followed by lessening of diarrhea. In most cases, changes occur within 1 wk of starting therapy, but the response may occasionally be delayed. Older patients and extremely ill patients tend to respond slowly, but once in remission the celiac child should be treated as a well child. Teenagers often become noncompliant. Unfortunately, this is an age when the disorder tends to be symptomatically quiescent, and a teenager may believe that the disorder has resolved. Nevertheless, mucosal damage is present. Subtle manifestations of growth failure or

delayed sexual maturation may take place when these patients ingest a gluten-containing diet. Appropriately diagnosed gluten-sensitive enteropathy is a lifelong condition requiring lifelong treatment. The development of malignancy secondary to long-standing celiac disease, especially with poor adherence to the strict gluten-free diet, is mostly a problem seen in the adult population. Malignancy affecting the esophagus, stomach, pharynx, and intestines is increased in patients with celiac disease. Intestinal lymphoma occurring in a 10-yr-old child with celiac disease has been reported. The observation that T-cell lymphoma can arise from long-standing celiac disease makes a gluten-free diet the best possible prophylaxis. Strict adherence to a gluten-free diet reduced the risk of all disease-associated cancers, including enteropathy-associated T-cell lymphoma. No complications from long-term gluten-free diet treatment are recognized.

320.9 Immunoproliferative Small Intestinal Disease

Immunoproliferative small intestinal disease (Mediterranean lymphoma) occurs most often in 10–30 yr olds in the Mediterranean basin, Mideast, Far East, and Africa. This is an IgA lymphoproliferative disorder that may progress to a B-cell lymphoma. Poverty and frequent episodes of gastroenteritis during infancy are antecedent social and medical problems. In some areas, as socioeconomic conditions have improved, the incidence of this disorder has decreased. Sporadic cases occur in Europe and North and South America, predominantly in immigrants from developing countries, although occasionally in native citizens. A similar disorder has been described in patients with AIDS.

Clinical Manifestations.

Initially, patients have intermittent diarrhea and abdominal pain. Later stages demonstrate persistent chronic diarrhea, malabsorption, protein-losing enteropathy, weight loss, digital clubbing, and growth failure.

Diagnosis.

Endoscopic biopsies of multiple duodenal and jejunal mucosal sites aid in the diagnosis. In addition, a serum marker (a heavy-chain paraprotein) of IgA is present in most cases. *Giardia lamblia* may also be present but is not responsible for the lymphoproliferative disorder. Immunosuppressed organ transplant recipients may develop a lymphoproliferative disorder manifesting diarrhea.

Treatment.

The earliest lesions respond to prolonged (~6 mo) tetracycline or metronidazole therapy. Prelymphomatous stages and lymphomas are treated with combination chemotherapy. Lymphoproliferative disorders in immunosuppressed transplant recipients usually improve with reduction of the immunosuppressive drug dose.

Prognosis.

Early therapy for antibiotic responsive lesions produces an excellent outcome. Treatment of the later lymphomatous lesions has resulted in a variable but usually poor outcome.

320.10 Other Malabsorptive Syndromes

Exocrine Pancreatic Insufficiency.

Cystic fibrosis is the most common congenital disorder associated with malabsorption. The next most common cause of pancreatic insufficiency in children, although much rarer, is Shwachman syndrome (see Chapter 330 and Chapter 331). Other rare disorders causing exocrine pancreatic insufficiency are Johanson-Blizzard syndrome (severe steatorrhea, aplasia of alae nasi, deafness, hypothyroidism, scalp defects), Pearson bone marrow syndrome (sideroblastic anemia, variable degree of neutropenia, thrombocytopenia), and isolated pancreatic enzyme deficiency (lipase, colipase, trypsinogen, amylase, lipase-colipase).

Intestinal Lymphangiectasia.

This group of disorders is characterized by dilatation of intestinal lymphatic vessels and leakage of lymph into the intestinal lumen and, at times, the peritoneal cavity. Because absorbed fat is normally transferred from the intestine through the lymphatic vessels, children with this disorder have steatorrhea with protein-losing enteropathy and may have lymphocyte depletion. Manifestations may include any combination of hypoalbuminemia, hypogammaglobulinemia, edema, lymphocytopenia, fat malabsorption, and chylous ascites. Intestinal lymphangiectasia can be primary or can result from abdominal or thoracic surgical damage to lymphatic vessels, chronic right-sided heart failure, constrictive pericarditis, retroperitoneal tumor, or malrotation with lymphatic obstruction. Primary intestinal lymphangiectasia is the result of a congenital abnormality of lymphatic drainage from the intestine and may be associated with abnormalities in lymphatic drainage from other regions of the body. Turner and Noonan syndromes have been associated with intestinal lymphangiectasia. Congenital intestinal lymphangiectasia in a premature infant presented as the cause of protein-losing enteropathy with hypoalbuminemia and generalized edema. It has also presented as a case of isolated fetal ascites. Intestinal lymphangiectasia should be included in the differential diagnosis when there is a history of peripheral edema and low serum albumin in a premature infant and when fetal ascites has occurred.

A few cases of intestinal B-cell lymphoma have been reported in adult patients with long-standing lymphangiectasia. The lymphoma responds well to surgery and postoperative chemotherapy.

The diagnosis is suggested by the typical findings described previously in association with an elevated fecal a_1 -antitrypsin level consistent with protein-losing enteropathy. The characteristic radiologic findings of uniform, symmetric thickening of mucosal folds throughout the small intestine are usually, although not always, present on small bowel contrast radiographs. The diagnosis is confirmed by the presence of collections of abnormal dilated lacteals with distortion of villi on per oral small bowel biopsy. The disorder may be seen only in the submucosa, thus requiring surgical biopsy of the intestine. Treatment is usually dietetic, limiting the amount of long-chain fat in the diet, which is normally absorbed by means of the intestinal lymphatics. This therapy reduces the volume of intestinal lymph and decreases the pressure within the dilated lymphatics. Patients are placed on a low-fat, high-protein, medium-chain triglyceride (MCT) diet. MCTs bypass the enteric lymphatics and directly enter the portal venous system. Special MCT-containing formulas can be used during infancy. Supplementing a low-fat diet with MCT oil used in cooking can be used in older children and adolescents.

Microvillus Inclusion Disease (Congenital Microvillus Atrophy).

Diarrheal diseases presenting in the neonatal period are listed in Table 320–4 .

Microvillus inclusion disease is a disorder that presents at birth with intractable, secretory, watery diarrhea and severe malabsorption. It appears to be the most common cause of persistent diarrhea that begins in the neonatal period. It has presented prenatally as what appeared to be a bowel obstruction in an ultrasound, with multiple fluid-filled dilated loops of bowel and with polyhydramnios. Postnatally there was no bowel obstruction, and the diagnosis was confirmed by electron microscopy (EM) of a small bowel biopsy.

The disorder seems to be inherited in an autosomal recessive pattern. The findings on small bowel biopsy are the key to the diagnosis and include villus atrophy, crypt hypoplasia, and the specific EM findings of microvillus inclusions (involutions) and increased secretory granules in enterocytes. The EM findings can also be seen in colonocytes. The somatostatin analogue octreotide has been used as treatment and may reduce the

TABLE 320.10-4 -- Diarrheal Diseases Presenting in the Neonatal Period

Condition	Clinical Features
Congenital microvillus atrophy	Intractable watery diarrhea
Tufting enteropathy	Intractable watery diarrhea
Intractable diarrhea with phenotypic abnormalities	Intractable watery diarrhea Low birth weight
Congenital glucose-galactose malabsorption	Acidic diarrhea
Congenital lactase deficiency	Acidic diarrhea
Congenital chloride diarrhea	Hydramnios, intractable watery diarrhea

Congenital defective jejunal Na^+/H^+ exchange	Hydramnios, intractable watery diarrhea
Congenital bile acid malabsorption	Steatorrhea
Congenital enterokinase deficiency	Failure to thrive, edema

Adapted from Schmitz J: Maldigestion and malabsorption. In Walker WA, Durie PR, Hamilton JR, et al (editors): Pediatric Gastrointestinal Disease, 3rd ed. Hamilton, Ontario, BC Decker, 2000, p 55.

volume of stool output in some infants. Epidermal growth factor has been used with equivocal results. The disease is fatal without long-term TPN. Even so, most children die in infancy or early childhood. Intestinal transplantation has become the only definitive treatment of this rare disease. A hepatic adenoma has been reported in a 14-yr-old patient with microvillous inclusion disease on life-long TPN. The patient eventually had a right hepatic lobectomy. There was a large 5 × 6-cm adenoma and six tiny 0.4–2.0?cm adenomas. Interestingly, liver histopathology revealed no significant fibrosis and no evidence of TPN liver disease in the noninvolved liver.

Autoimmune Enteropathy.

Autoimmune enteropathy is a poorly characterized syndrome of chronic diarrhea and malabsorption. If symptoms initially develop after the first 6 mo of life, the disorder is likely to be mistaken for gluten-sensitive enteropathy. Typically, the lack of response to a gluten-free diet leads to further evaluation. Histologic findings in the small bowel include partial or complete villous atrophy, crypt hyperplasia, and an increase in chronic inflammatory cells in the lamina propria. Specific serum antienterocyte antibodies may be identified in 50% or more of patients by indirect immunofluorescent staining of normal small bowel mucosa and the kidney. The colon can also be involved. Extraintestinal autoimmune disorders are usual and include arthritis, membranous glomerulonephritis, insulin-dependent diabetes, thrombocytopenia, autoimmune hepatitis, hypothyroidism, and hemolytic anemia. Treatment has included prednisone, azathioprine, cyclophosphamide (Cytoxan), cyclosporine, and tacrolimus.

Tufting Enteropathy.

Tufting enteropathy (intestinal epithelial dysplasia) is a disorder that presents in the first weeks of life with persistent watery diarrhea and appears to account for a small fraction of infants with protracted diarrhea of infancy. Onset of symptoms is not immediately after birth as in microvillus inclusion disease. On small bowel biopsy, the distinctive feature is that 80–90% of the epithelial surface contains focal epithelial “tufts” (teardrop-shaped groups of closely packed enterocytes with apical rounding of the plasma membrane). In other known enteropathies, tufts are seen on 15% or less of the epithelial surface. In this disorder, colonic epithelium shows no abnormality. On electron microscopy of small bowel epithelium, the major finding is shortening of the microvilli. This does not appear to be an autoimmune enteropathy, and no known enteropathogens have been isolated. The intestinal lesion has not responded to removal of dietary antigens or use of immunosuppressive therapy. This may be a disorder of cell-cell and cell matrix interactions. This neonatal diarrhea that resists all treatments requires permanent parenteral nutrition; it is another indication for intestinal transplantation.

Endocrine Disorders.

Steatorrhea may occur with a number of endocrine disorders, including adrenal insufficiency, hypoparathyroidism, and diabetes mellitus.

Tropical Sprue.

This syndrome is characterized by generalized malabsorption associated with a diffuse lesion of the small intestinal mucosa that occurs only in persons who have lived in or visited certain tropical regions. The disease is rare in children. Tropical sprue is endemic in numerous locales in the tropics extending from the equator to both the north and south slightly more than 30° latitude to include the Caribbean, India, and southern Africa. The disease is particularly present in Cuba, the Dominican Republic, Haiti, and Puerto Rico, yet it has not been observed in Jamaica. It has also been well described in Colombia and Venezuela. Perhaps the most extensive documentation of tropical sprue has been that in India. Besides occurring in indigenous populations, tropical sprue is contracted by those who visit the tropics for a month or longer. Although most cases tend to arise sporadically in endemic form, a significant proportion of individuals in the tropical regions (5–10%) may contract the disease. Epidemics have been reported, particularly from India, and are said to occur as a sequela of an outbreak of acute diarrheal disease. The available evidence suggests that this disorder is an infectious disease resulting from persistent contamination of the small bowel by strains of *Klebsiella pneumoniae*, or less often by *Escherichia coli* or *Enterobacter cloacae*. Their eradication by antimicrobial therapy cures the intestinal abnormalities. Fever and malaise precede the onset of watery diarrhea. In about 1 wk, acute features subside and chronic malabsorption, intermittent diarrhea, and anorexia lead eventually to severe malnutrition. Signs of malnutrition may include night blindness, glossitis, stomatitis, cheilosis, hyperpigmentation, and edema. Muscle wasting is marked, and the abdomen is often distended. Patients have evidence of diffuse malabsorption, abnormal exocrine pancreatic function contributing to the steatorrhea, and carbohydrate intolerance. Megaloblastic anemia is the result of folate and vitamin B_{12} deficiencies. Small bowel biopsy abnormalities are more prominent in the jejunum than in the ileum early on, but subsequently the entire bowel is affected (unlike in celiac disease). Histology is similar to celiac disease, but completely flat mucosa is observed in only 10% of cases. There are reports of a thickened basement membrane and the accumulation of triglycerides subjacent to the surface epithelium. This feature is quite typical and differs from the intraenterocyte accumulation of lipid droplets observed in celiac disease and in patients with marasmus or kwashiorkor. Treatment includes folate and vitamin B_{12} therapy. To reverse all aspects of the malabsorption syndrome and prevent recurrence requires 6 months of therapy with oral folic acid (5?mg) and tetracycline or sulfonamides. Relapses, requiring additional courses of therapy, will

occur in 10–20% of patients who continue to reside in an endemic tropical region.

Wolman Disease.

This rare lethal lipid storage disease leads to lipid accumulation in many organs, including the small intestine. In addition to vomiting, severe diarrhea, and hepatosplenomegaly, patients may have steatorrhea as the result of lymphatic obstruction. Deficiency of lysosomal acid lipase is the cause of the disease (see Chapter 75). Successful long-term bone marrow engraftment has resulted in the normalization of peripheral leukocyte lysosomal acid lipase enzyme activity with subsequent resolution of the diarrhea and restoration of developmental milestones.

320.11 Enzyme Deficiencies

Enterokinase Deficiency.

Congenital deficiency of this small intestinal enzyme has been reported in a few children. The disease results in a complete absence of pancreatic proteolytic activity

---

because enterokinase is an essential activator of pancreatic trypsinogens. Affected patients are ill from very early life with severe diarrhea and failure to thrive. Hypoproteinemia is common and may lead to edema. In duodenal fluid, tryptic activity is missing, whereas lipase and amylase are normal; in vitro tryptic activity of the fluid can be restored by the addition of enterokinase. Malabsorption of protein is the major defect, although mild steatorrhea has been reported. Pancreatic enzyme replacements restore normal digestive function; much smaller amounts are needed compared with those required for pancreatic insufficiency.

Disaccharidase Deficiencies.

The disaccharidases are located on the brush border membrane surface of the small bowel. Occasionally, congenital deficiencies occur, but abnormal disaccharidase activities in infants and young children have most often been the result of diffuse acquired lesions of the intestinal epithelium, such as those of infection or celiac disease. In older children and adults, late-onset genetic lactase deficiency is the most common condition associated with reduced disaccharidase activity.

The *clinical manifestations* of significant disaccharidase deficiency (disaccharide intolerance) are similar whatever its cause or the enzymes involved. If disaccharide hydrolysis at the brush border is incomplete, the sugar accumulates in the distal intestinal lumen, where organic acids and hydrogen gas are produced by bacteria. The excess intraluminal sugar and organic acids draw water into the lumen, leading to watery osmotic diarrhea with stools that are of low pH (pH < 5.6), contain excess sugar, and tend to excoriate the buttocks. Patients may have bloating and borborygmi, but steatorrhea is rare. In some cases, particularly those beyond infancy, gas production causing crampy abdominal pain is the dominant problem, rather than diarrhea.

If the disaccharide involved is a reducing sugar (lactose), the standard Clinitest examination will be 2+ or greater in most cases. Disaccharidase activities can be assayed in mucosal biopsy specimens. Breath hydrogen excretion after an oral sugar load is a useful noninvasive technique for detecting disaccharide intolerance (see Chapter 320.1).

Lactase Deficiency.

Congenital absence of lactase has been reported in a few cases. The usual mechanism for primary lactose intolerance relates to the *developmental* pattern of lactase activity. Because lactase activity rises relatively late in fetal life and begins to fall after the age of 3 yr, intolerance to lactose can be anticipated in extremely premature infants and in some older children and adults. Approximately 15% of adult whites, 40% of adult Asians, and 85% of adult blacks in the United States are deficient in intestinal lactase; this is known as “adult-onset hypolactasia” and is an autosomal recessive characteristic. Because lactase activity in the mucosa is at best marginal, this enzyme is particularly likely to be depleted *secondary to diffuse mucosal diseases.*

Clinical manifestations occur in response to ingestion of lactose, the sugar in milk. Explosive watery diarrhea is associated with abdominal distention, borborygmi, flatulence, and an excoriated diaper area. A syndrome of recurrent, vague, crampy abdominal pain has also been attributed to lactose intolerance. School-aged and preschool-aged children experience episodic mid-abdominal pain. Usually, their general health is unaffected, and they may have no obvious temporal relationship of pain or diarrhea with milk ingestion.

Treatment consists of removal of milk from the diet. In most cases the elimination need not be total; stopping ingestion of milk as a beverage is important. A lactase preparation is available in prepackaged milk with 100% of the lactose predigested; it allows asymptomatic consumption of modest quantities of milk incubated with the added enzyme. A tablet with lactase activity can also be ingested with meals. Live culture yogurt contains bacteria that produce lactase enzyme and is, thus, frequently tolerated by lactase-deficient individuals.

Sucrase-Isomaltase Deficiency.

The only relatively common congenital deficiency of disaccharidase activities, a combined deficiency of sucrase and isomaltase, is inherited as an autosomal recessive trait and has been mapped to chromosome 3. Prevalence is the highest in the native populations of Alaska, Canada, and Greenland. It occurs in about 0.2% of North Americans. Symptoms usually begin when a sucrose or glucose polymer-containing diet is started. Patients may be intolerant to starch, but because isomaltase acts only on the branch points of the starch molecule, isomaltase deficiency itself is relatively asymptomatic. The symptoms are bloating, watery diarrhea, and failure to thrive. Recurrent abdominal pain has not been attributed to sucrose-isomaltose intolerance. Because sucrose is not a reducing sugar, its presence is not detected in the stool by Clinitest unless the specimen is first hydrolyzed with hydrochloric acid. The morphologic features of the small intestinal

mucosa are normal, but enzyme assays show specific deficiencies of sucrase and isomaltase with normal levels of lactase and maltase. Breath testing usually demonstrates increased hydrogen gas after sucrose ingestion. Affected patients improve quickly after dietary sucrose is reduced to minimal amounts.

Oral replacement of genetically determined sucrase deficiency, which is part of congenital sucrase isomaltase deficiency (CSID) is available as Sucraid (sacrosidase), an oral solution, which is the only therapy approved by the U.S. Food and Drug Administration.

Sacrosidase significantly decreased breath H_2 excretion in CSID patients. Higher concentrations of sacrosidase were associated with fewer stools, fewer symptoms of gas, abdominal cramps, and bloating compared with lower concentrations and with placebo. Sacrosidase is safe and effective in preventing gastrointestinal symptoms in patients with CSID consuming a normal diet.

320.12 Defects of Absorption or Transport

Glucose-Galactose Malabsorption.

More than 30 different mutations of the sodium/glucose co-transporter gene *(SGLT1)* have been identified to cause this rare autosomal recessive, congenital disorder of intestinal glucose-galactose absorption. *SGLT1* couples glucose and galactose transport to the sodium gradients across intestinal and renal brush borders. Renal tubular epithelium is affected to a lesser degree. The identification of mutations of *SGLT1* makes it possible to carry out prenatal screening in families at risk for the disease.

The selective defect in the intestinal glucose and galactose/ Na^+ co-transport systems leads to osmotic diarrhea, which follows the ingestion of glucose, breast milk, or conventional formulas soon after birth, because most dietary sugars are polysaccharides or disaccharides with glucose or galactose moieties. The patient may be bloated; and, if diarrhea persists, dehydration and acidosis can be severe, resulting in death. The stools are acidic and contain sugar. Patients with the defect have normal absorption of fructose; their small bowel function and structure are normal in all other aspects. Intermittent or permanent glycosuria after fasting or after a glucose load is a frequent finding. Thus, the finding of positive reducing substances in watery stools and slight glycosuria despite low blood sugar levels is highly suggestive of glucose-galactose malabsorption. Malabsorption of glucose and galactose is easily identified using the breath hydrogen test. It is safe to perform the first test with a dose of 0.5?gm/kg of glucose; if necessary, a second test can be performed using 2?g/kg. Breath H_2 will rise more than 20?ppm if a patient has this defect. The diagnosis can be confirmed later by

small intestinal biopsy showing (1) normal villous architecture, (2) normal disaccharidase activities, and (3) an absorptive defect confined to glucose and galactose. *Treatment* consists of rigorous restriction of glucose and galactose. Fructose, the only carbohydrate that can be given safely, should be added to a carbohydrate free formula at a concentration of 6–8%. Diarrhea immediately ceases when infants are given such a formula. Although the defect is permanent, later in life limited amounts of glucose (e.g., in starches) or sucrose may be tolerated.

Severe diffuse mucosal damage, particularly in a young infant, may also impair the glucose-galactose carrier sufficiently to cause intolerance to these sugars. Usually, if mucosal damage is severe enough to impair glucose transport, other absorptive processes are affected.

Abetalipoproteinemia (see Chapter 75.3).

This rare autosomal recessive disorder of lipoprotein metabolism is associated with severe fat malabsorption from birth. Children fail to thrive during the 1st yr of life, and their stools are pale, foul smelling, and bulky. The abdomen is distended, and deep tendon reflexes are absent as a result of peripheral neuropathy.

Intellectual development tends to be slow. After 10 yr of age, intestinal symptoms are less severe, ataxia develops, and one sees a loss of position and vibration senses and the onset of intention tremors. These last symptoms reflect involvement of the posterior columns, cerebellum, and basal ganglia. In adolescence, atypical retinitis pigmentosa develops.

Diagnosis rests on finding acanthocytes in the peripheral blood and extremely low plasma levels of cholesterol (<50?mg/dL); triglycerides are very low (<20?mg/dL). Chylomicrons and very-low-density lipoproteins are not detectable, and the low-density lipoprotein (LDL) fraction is virtually absent from the circulation; marked triglyceride accumulation in villus enterocytes occurs in the fasting duodenal mucosa. Usually, steatorrhea occurs in younger patients but other processes of assimilation are intact. Rickets may be an unusual initial manifestation of abetalipoproteinemia and hypobetalipoproteinemia. Rickets is caused by steatorrhea-induced calcium losses. Patients have mutations of the microsomal triglyceride transfer protein (MTP) gene, resulting in absence of MTP function in the small bowel. This protein is required for normal assembly and secretion of very-low-density lipoproteins and chylomicrons. The neuropathy is the result of vitamin E deficiency.

Specific *treatment* is not available. Large supplements of the fat-soluble vitamins A, D, E, and K should be given. Vitamin E (100–200?mg/kg/24?hr) and vitamin A (10,000–25,000?IU/day) may arrest the neurologic and retinal degeneration. Limiting long-chain fat intake may alleviate intestinal symptoms; medium-chain triglycerides can be used to supplement the fat intake.

Homozygous Hypobetalipoproteinemia.

This disorder is transmitted as an autosomal dominant trait; the homozygous form is indistinguishable from abetalipoproteinemia. However, the parents of these patients, as heterozygotes, have reduced plasma low-density lipoprotein and apoprotein-ß concentrations, unlike the parents of patients with abetalipoproteinemia, who have normal levels. On EM of small bowel biopsies, the general size of the lipid vacuoles can differentiate between abetalipoproteinemia and hypobetalipoproteinemia: many small vacuoles are present in hypobetalipoproteinemia, and large vacuoles are seen

in abetalipoproteinemia.

Chylomicron Retention Disease.

In this rare recessive disorder, the processes leading up to the release of chylomicrons from enterocytes appear to be defective. These patients have severe intestinal symptoms with steatorrhea, chronic diarrhea, and failure to thrive. Acanthocytosis is rare, and neurologic manifestations are less severe than those observed in abetalipoproteinemia. Plasma cholesterol levels are reduced, but moderately so (<75?mg/dL); fasting triglycerides are normal; but the fat-soluble vitamins, particularly A and E, rapidly deplete. Early aggressive therapy with fat-soluble vitamins and modification of dietary fat intake is indicated, identical to the treatment for abetalipoproteinemia.

Amino Acid Transport Defects.

In several of the specific congenital disorders of amino acid transport (see Chapter 74), defective intestinal amino acid transport occurs. At least three specific small bowel carriers appear to be involved in active transport of amino acids. Amino acid uptake into the intestinal mucosa is defective in *cystinuria,* but these patients have no gastrointestinal symptoms. In *Hartnup disease,* malabsorption of neutral amino acids including tryptophan leads to ataxia, intellectual deterioration, a pellagra-like rash, and, at times, diarrhea. The clinical manifestations are due to the malabsorption of tryptophan, producing nicotinamide deficiency. Administration of nicotinamide, given orally, leads to a dramatic clinical improvement. *Methionine malabsorption* is associated with episodes of diarrhea in fair-complexioned, retarded children whose urine has a sweet odor and contains excess ß-hydroxybutyric acid. In the *blue diaper syndrome,* tryptophan absorption is defective.

Vitamin B_{12} Malabsorption.

Causes of vitamin B_{12} deficiency fall into three categories: (1) decreased intake (e.g., breast-fed babies whose mothers have undiagnosed vitamin B_{12} deficiency because of strict vegetarian diets); (2) abnormal absorption (e.g., absence/dysfunction of intrinsic factor [past gastric resection, autoimmune pernicious anemia]; decreased gastric acid secretion secondary to H_2 receptor antagonists, proton-pump inhibitors; competition for B_{12} in the intestine [bacterial overgrowth]; disruption of absorption across the ileal surface [Crohn disease, tropical sprue]); and (3) inborn errors of vitamin B_{12} transport and metabolism.

Several rare congenital defects may affect assimilation of vitamin B_{12} . These conditions are much less common than dietary vitamin B_{12} deficiency or malabsorption secondary to terminal ileal resection or dysfunction. In *juvenile pernicious anemia,* intrinsic factor production in the stomach is defective. Vitamin B_{12} malabsorption results, leading to megaloblastic anemia and growth failure. Gastric structure and function are otherwise normal.

Transcobalamin II deficiency is an inherited defect of a protein necessary for intestinal transport of vitamin B_{12} . The result is severe megaloblastic anemia, diarrhea, and vomiting.

Imerslund syndrome occurs in patients in whom ileal absorption of vitamin B_{12} is defective. Ileal structure and function are otherwise normal. Megaloblastic anemia develops toward the end of the 1st yr. Proteinuria is commonly associated.

Treatment of these disorders is to administer vitamin B_{12} by injection: 1,000?µg/twice weekly for transcobalamin II deficiency and 100?µg/mo for the others. Once patients are in hematologic remission after intramuscular vitamin B_{12} therapy, they can receive *intranasal* vitamin B_{12} , 500?µg, in once weekly metered doses.

Congenital Malabsorption of Folic Acid.

Isolated congenital folate malabsorption, described in fewer than 20 patients, may be the consequence of a selective defect in intestinal and blood-brain barrier folate transport. Inheritance studies suggest an autosomal recessive disorder.

The main constant clinical feature is severe megaloblastic anemia that may begin by the age of 3 mo. Neurologic symptoms may include ataxia, convulsions, mental retardation, and intracranial calcifications. Gastrointestinal symptoms may present in the 1st week of life and include mouth ulcers, diarrhea, and failure to thrive. Diagnosis is made by lack of an increase in serum or cerebrospinal fluid (CSF) folate after a loading test with oral folic acid (5?mg). Early and aggressive use of parenteral folinic acid is the treatment of choice, and documentation of

---

improvement of CSF folate is critical if a good outcome is possible. Subsequent treatment, aimed at maintaining levels of folate in serum, red blood cells, and CSF, is by using large (up to 100?mg/day) oral doses of folic, folinic, or methyltetrahydrofolic acid.

Chloride-Losing Diarrhea.

This rare recessive inherited disorder caused by mutations in a chromosome 7 gene, first known as *DRA* (for Down Regulated in Adenoma), involves an abnormality of the chloride/bicarbonate transport mechanism in the cell surface. This congenital defect of distal ileal and colonic chloride transport is associated with maternal polyhydramnios. The dominant symptom is severe watery diarrhea beginning at birth, the result of accumulation of chloride ion in the intestinal lumen. Watery diarrhea leads to dehydration and a severe electrolyte disturbance characterized by hypokalemia, hypochloremia, and alkalosis, a most unusual pattern for a child with chronic diarrhea. Other aspects of intestinal absorption are normal. Stools contain chloride in excess of the sum of sodium and potassium (125–150?mEq/L). Treatment does not alter diarrhea but diminishes complications. All losses of electrolytes and water are replaced intravenously at first; oral solutions are usually tolerated after a month. If the diagnosis is made early in the neonatal period and adequate therapy started immediately, the affected infant will show perfect growth

and development.

Congenital Sodium Diarrhea.

A few patients have been described with profuse watery, secretory diarrhea from birth. There was maternal polyhydramnios and neonatal abdominal distention; however, unlike chloride diarrhea, this condition was characterized by acidosis and fecal chloride concentration less than sodium concentration (as high as 145?mEq/L). *Treatment* with oral hydration solution was effective in maintaining normal growth. The apparent basis for this rare syndrome is a defect in sodium-hydrogen exchange in the small intestine and colon.

Vitamin D–Dependent Rickets.

In this autosomal recessive disorder, a specific defect in the metabolism of vitamin D causes malabsorption of calcium (see Chapter 697). Intestinal function is otherwise normal.

Primary Hypomagnesemia.

This specific intestinal transport defect in magnesium transport causes severe hypomagnesemia and, secondarily, hypocalcemic tetany in infancy. Other aspects of intestinal function are normal. The findings are reversed by large supplements of magnesium, which must be continued indefinitely.

Acrodermatitis Enteropathica (see also Chapter 649).

This unusual constellation of clinical findings is due to zinc deficiency secondary to zinc malabsorption. Early in life, the patient experiences rashes around mucocutaneous junctions and on the extremities; alopecia, chronic diarrhea, and sometimes steatorrhea may occur. If not treated, the patient fails to thrive. Serum zinc concentration and alkaline phosphatase activity are low. Intestinal mucosal biopsy specimens show Paneth cell inclusions that disappear after treatment. An oral supplement of zinc sulfate, 1–2?mg elemental zinc/kg/24?hr, causes rapid healing of the skin lesions and improvement of diarrhea.

Menkes (Kinky Hair) Syndrome.

This rare recessively inherited disorder is characterized by growth retardation, abnormal hair, cerebellar degeneration, severe vasculopathy, fractures, and early death (see Chapter 592.5). Orally ingested copper accumulates in the intestines, and there is defective copper absorption. Its pathogenesis is unclear, but a widespread defect in cellular copper transport affects the intestine as well as other tissues. There is decrease of the cuproenzyme activities. The blood, liver, and brain are deprived of copper and, thus, are in a state of copper deficiency. Serum copper and ceruloplasmin levels are low, but cellular copper content is increased. The currently accepted treatment is the administration of parenteral copper; few patients avoid the neurologic sequelae.

Bile Acid Malabsorption.

Primary bile acid malabsorption caused by mutations in the ileal sodium-dependent bile acid transporter gene results in diarrhea and steatorrhea from early infancy. These patients have reduced plasma cholesterol levels and severe growth retardation as well.

Drug-Induced Absorptive Defects.

Some drugs have a diffuse impact on the small intestinal epithelium. For example, methotrexate can cause arrest of enterocyte mitoses and can result in a mucosal lesion; large doses of neomycin also affect mucosal structure. *Sulfasalazine* interferes with folic acid absorption. *Cholestyramine* binds bile salts and calcium in the intestinal lumen to cause hypocalcemia and steatorrhea. *Phenytoin* interferes with calcium absorption and can cause rickets.

Enterocyte Heparan Sulfate Deficiency and the Carbohydrate-Deficient Glycoprotein Syndrome.

Congenital enterocyte heparan deficiency (CEHD) is a rare cause of intractable diarrhea with protein-losing enteropathy. Heparan sulfate is a glycosaminoglycan; such glycosaminoglycans have multiple roles within the intestine, including restriction of charged macromolecules, such as albumin, within the vascular lumen.

CEHD may be an unusual presentation of the carbohydrate deficient glycosylation syndrome (CDGS) type 1 (also known as Jaeken syndrome) (see Chapter 76.6). This latter condition in which glycan chain formation is impaired can be detected by aberrant glycosylation of serum transferrin. The disorder normally presents as mental retardation, but there is a highly variable phenotype. CDGS is usually accompanied by severe neurologic abnormalities (hypotonia, muscular weakness, developmental retardation). Blood coagulation disorders are a common feature of CDGS type 1a. One child with CDGS type 1b had no neurodevelopmental problems but rather predominantly intestinal problems (protein-losing enteropathy). She responded to oral mannose treatment, whereas other forms of CDGS have no known treatment. Any child with unexplained protein-losing enteropathy, or when there is an abnormality in another system (e.g., severe neurodevelopmental delay; altered blood clotting parameters), should have transferrin glycosylation checked.

Chapter 321 - Gastroenteritis

Larry K. Pickering
John D. Snyder

Infections of the gastrointestinal tract are caused by a wide variety of enteropathogens, including bacteria, viruses, and parasites. Clinical manifestations depend on the organism and host response to infection and include asymptomatic infection, watery diarrhea, bloody diarrhea, chronic diarrhea, and extraintestinal manifestations of infection. A presumptive etiologic diagnosis can be established from epidemiologic clues, clinical manifestations, physical examination, and knowledge of the pathophysiologic mechanisms of enteropathogens. Laboratory studies used to identify diarrheal pathogens are often not required because most episodes are self-limited. All patients with diarrhea require fluid and electrolyte therapy, a few need other nonspecific support, and some may benefit from antimicrobial therapy.

Etiology.

The two basic types of acute infectious diarrhea are noninflammatory and inflammatory. Enteropathogens elicit **noninflammatory diarrhea** through enterotoxin production by some bacteria, destruction of villus (surface) cells by viruses, adherence by parasites, and adherence and/or translocation by bacteria. In contrast, **inflammatory diarrhea** usually is caused by bacteria that invade the intestine directly or produce cytotoxins. Some enteropathogens possess more than one virulence property.

Acute diarrhea or diarrhea of short duration may be associated with any of the recognized bacterial, viral, or parasitic causes of enteritis (Box 321–1). Chronic or persistent diarrhea lasting 14 days or more may be due to (1) an infectious agent such as *Giardia lamblia, Cryptosporidium parvum,* and enteroaggregative or enteropathogenic *Escherichia coli*; (2) any enteropathogen that infects an immunocompromised host; or (3) residual symptoms due to damage to the intestine by an enteropathogen after an acute infection. There also are many noninfectious causes of diarrhea in children (Box 321–2).

BACTERIAL ENTEROPATHOGENS.

Bacterial enteropathogens may cause either inflammatory or noninflammatory diarrhea, and specific enteropathogens may be associated with either clinical form. Generally, inflammatory diarrhea is associated with *Aeromonas*, *Campylobacter jejuni, Clostridium difficile,* enteroinvasive *E. coli,* Shiga toxin–producing *E. coli* (*E. coli* O157:H7), *Plesiomonas shigelloides, Salmonella*, *Shigella*, *Vibrio parahaemolyticus,* and *Yersinia enterocolitica.* Noninflammatory diarrhea may be caused by enteropathogenic *E. coli,* enterotoxigenic *E. coli, Vibrio cholerae,* and several of the pathogens associated with inflammatory diarrhea. Antimicrobial therapy is administered to select patients with bacterial enteritis to shorten the clinical course, to

decrease excretion of the causative organism, or to prevent complications (Table 321–1). *Helicobacter pylori* infects gastric mucosa and is associated with gastritis, peptic ulcer disease, and gastric cancer (see Chapter 316).

VIRAL ENTEROPATHOGENS.

The main causes of viral gastroenteritis include rotavirus, enteric adenovirus, astrovirus, Norwalk agent–like virus, and calicivirus. Cytomegalovirus and herpes simplex virus have been associated with diarrhea and other gastrointestinal tract signs and symptoms, generally in immunocompromised hosts.

PARASITIC ENTEROPATHOGENS.

G. lamblia is the most common parasitic cause of diarrhea in the United States; other parasitic pathogens include *Entamoeba histolytica, Strongyloides stercoralis, Balantidium coli,* and spore-forming protozoa, which include *Cryptosporidium parvum, Cyclospora cayetanensis, Isospora belli, Enterocytozoon bieneusi,* and *Encephalitozoon intestinalis.* The latter three agents have been found most often in persons with AIDS. The role of *Dientamoeba fragilis* and *Blastocystis hominis* as causes of diarrhea has not been defined fully. *Balantidium coli, Trichuris trichiura,* and *E. histolytica* can produce bloody diarrhea in humans.

Patients with diarrhea normally do not need to have their stools examined for ova and parasites unless they (1) have a history of recent travel to an endemic area, stool cultures are negative for other enteropathogens, and diarrhea persists for more than 1 wk; (2) are part of an outbreak of diarrhea; or (3) are immunocompromised. Examination of more than one

TABLE 321-1 -- Antimicrobial Therapy for Bacterial Enteropathogens in Children

Organism[*]	Antimicrobial Agent	Indication for Antimicrobial Therapy
Aeromonas	TMP/SMZ	Dysentery-like illness, prolonged diarrhea
Campylobacter	Erythromycin[†] or azithromycin	Early in the course of illness
Clostridium difficile	Metronidazole or vancomycin	Moderate to severe disease
Escherichia coli		
Enterotoxigenic	TMP/SMZ[†]	Severe or prolonged illness
Enteropathogenic	TMP/SMZ[†]	Nursery epidemics, life-threatening illness

Enteroinvasive	TMP/SMZ[‡]	All cases if organism susceptible
Salmonella	Cefotaxime or ceftriaxone or ampicillin or chloramphenicol or TMP/SMZ[‡]	Infants <3 mo patients, typhoid fever *(Salmonella typhi)*, bacteremia, dissemination with localized suppuration
Shigella	Ampicillin or ciprofloxacin[‡] or ofloxacin or ceftriaxone	All cases if organism susceptible
Vibrio cholerae	Doxycycline or tetracycline	All cases

TMP/SMZ = trimethoprim and sulfamethoxazole.

**Susceptibility testing should be performed on all organisms*
†Quinolones (ciprofloxacin or ofloxacin) may be used for persons =18 yr of age.

stool specimen may be necessary to establish a diagnosis. Certain medications, antidiarrheal compounds, and barium may interfere with identification of parasitic enteropathogens.

Treatment of these infections depends on the clinical condition and availability of effective therapy (Table 321–2). Antimicrobial resistance is present in many parts of the world.

Epidemiology.

Diarrheal diseases are one of the leading causes of morbidity and mortality in children worldwide, causing 1 billion episodes of illness and 3–5 million deaths annually. The relative importance and epidemiologic characteristics of diarrheal pathogens vary by geographic location. In the United States each year, 20–35 million episodes of diarrhea occur among the 16.5 million children younger than 5 yr of age, resulting in 2.1–3.7 million physician visits, 220,000 hospitalizations, 924,000 hospital days, and 300–400 deaths. Children in developing countries become infected with a diverse group of bacterial and parasitic pathogens, whereas all children in developed as well as developing countries acquire rotavirus and, in many cases, other viral enteropathogens, *G. lamblia,* and *C. parvum* during their first 5 yr of life.

The major mechanisms of transmission for diarrheal pathogens are person to person through the fecal-oral route or by ingestion of contaminated food or water. Enteropathogens that are infectious in a small inoculum *(Shigella, E. coli* O157:H7, enteric viruses, *G. lamblia, C. parvum,* and *E. histolytica)* may be transmitted by person-to-person contact. Factors that increase susceptibility to infection with enteropathogens include young age, immune deficiency, measles, malnutrition, travel to an endemic area, lack of breast-feeding, exposure to unsanitary conditions, ingestion of contaminated food or water, level of maternal education, and attendance at a childcare center.

General Approach to Children with Acute Diarrhea.

Enteric infections cause gastrointestinal tract signs and symptoms as well as extraintestinal complications, including neurologic manifestations. Gastrointestinal tract involvement may include diarrhea, abdominal cramps, and vomiting. Systemic manifestations are varied and associated with a variety of causes. Extraintestinal infections related to bacterial enteric pathogens include vulvovaginitis, urinary tract infection, endocarditis, osteomyelitis, meningitis, pneumonia, hepatitis, peritonitis,

chorioamnionitis, soft tissue infection, and septic thrombophlebitis. Neurologic manifestations of infectious enteritis include paresthesias (from ingestion of fish, shellfish, monosodium glutamate), hypotonia and descending muscle weakness *(C. botulinum),* and a variety of other signs and symptoms (from ingestion of fish, shellfish, and mushrooms). Immune-mediated extraintestinal manifestations of enteric pathogens usually occur after diarrhea has resolved (Table 321–3). Hemolytic uremia syndrome may follow infection with *E. coli* or *Shigella* (Chapter 510).

The main objectives in the approach to a child with acute diarrhea are to (1) assess the degree of dehydration and provide fluid and electrolyte replacement, (2) prevent spread of the enteropathogen, and (3) in select episodes determine the etiologic agent and provide specific therapy if indicated. Information about oral intake, frequency and volume of stool output, general appearance and activity of the child, and

TABLE 321-2 -- **Antimicrobial Therapy for Enteric Parasites in Children**

Organism	**Antimicrobial Agent**
Giardia lamblia	Furazolidone or metronidazole or albendazole or quinacrine or paromomycin (pregnancy)
Entamoeba histolytica	Metronidazole followed by iodoquinol
Blastocystis hominis	Metronidazole or iodoquinol
Cryptosporidium parvum	Paromomycin or azithromycin may be indicated in immunocompromised hosts.
Cyclospora cayetanensis	Trimethoprim/sulfamethoxazole (TMP/SMZ)
Isospora belli	TMP/SMZ
Enterocytozoon bieneusi	Albendazole
Encephalitozoon intestinalis	Albendazole (minimally effective)
Strongyloides stercoralis	Ivermectin or thiabendazole

HUS	*S. dysenteriae 1, E. coli*

HUS = hemolytic uremia syndrome.

frequency of urination must be obtained. Data should be obtained about childcare center attendance, recent travel to a diarrhea endemic area, use of antimicrobial agents, exposure to contacts with similar symptoms, and intake of seafood, unwashed vegetables, unpasteurized milk, contaminated water, or uncooked meats. The duration and severity of diarrhea, stool consistency, presence of mucus and blood, and other associated symptomatology, such as fever, vomiting, and seizures, should be determined. Fever is suggestive of an inflammatory process and also occurs as a result of dehydration. Nausea and emesis are nonspecific symptoms, but vomiting suggests organisms that infect the upper intestine, such as enteric viruses, enterotoxin-producing bacteria, *Giardia,* and *Cryptosporidium.* Fever is common in patients with inflammatory diarrhea, abdominal pain is more severe, and tenesmus may occur in the lower abdomen and rectum, indicating involvement of the large intestine. Emesis is common in noninflammatory diarrhea; fever usually is absent or low grade; pain is crampy, periumbilical, and not severe; and diarrhea is watery, indicating upper intestinal tract involvement. Because immunocompromised patients require special consideration, information about an underlying immunodeficiency or chronic disease is important. **Chronic diarrhea** is defined as diarrhea lasting more than 14 days.

EXAMINATION OF STOOL.

Stool specimens should be examined for mucus, blood, and leukocytes, the presence of which indicates colitis. Fecal leukocytes are produced in response to bacteria that diffusely invade the colonic mucosa. A positive fecal leukocyte examination indicates the presence of an invasive or cytotoxin-producing organism such as *Shigella, Salmonella, C. jejuni,* invasive *E. coli, C. difficile, Y. enterocolitica, V. parahaemolyticus,* and possibly *Aeromonas* or *P. shigelloides.* Not all patients with colitis have positive results on fecal leukocyte examination. Patients infected with

Shiga toxin–producing *E. coli* and *E. histolytica* generally have minimal fecal leukocytes.

Stool cultures should be obtained as early in the course of disease as possible from patients in whom the diagnosis of hemolytic-uremic syndrome (HUS) is suspected, in patients with bloody diarrhea, if stools contain fecal leukocytes, during outbreaks of diarrhea, and in persons who have diarrhea and are immunosuppressed. Fecal specimens that cannot immediately be plated for culture can be transported to the laboratory in a non–nutrient–holding medium such as Cary-Blair to prevent drying.

Because certain bacterial agents, including *Y. enterocolitica, V. cholerae, V. parahaemolyticus, Aeromonas*, *C. difficile, E. coli* O157: H7, and *Campylobacter*, require modified laboratory procedures for identification, laboratory personnel should be notified when one of these organisms is the suspected etiologic agent. Serotype and toxin assays are available for further characterization of *E. coli*. Detection of *C. difficile* toxins is valuable in the diagnosis of antimicrobial-associated colitis. Proctosigmoidoscopy may be helpful in establishing a diagnosis in patients in whom symptoms of colitis are severe or the cause of an inflammatory enteritis syndrome remains obscure after initial laboratory evaluation.

MANAGEMENT OF FLUIDS AND ELECTROLYTES AND REFEEDING

(also see Chapter 47 and Chapter 48.1). Management of dehydration remains the cornerstone in the approach to patients with diarrhea. Children, especially infants, are more susceptible than adults to dehydration because of the greater basal fluid and electrolyte requirements per kilogram and because they are dependent on others to meet these demands. Patients with diarrhea and possible dehydration should be evaluated to assess the degree of dehydration as evident from clinical signs and symptoms, ongoing losses, and daily requirements.

Oral hydration usually is the treatment of choice for all but the most severely dehydrated patients whose caretakers cannot administer fluids. Rapid rehydration with replacement of ongoing losses during the first 4–6?hr should be carried out using an appropriate oral rehydration solution. Once a patient is rehydrated, an orally administered maintenance solution should be used (see Table 48–1). Home remedies including decarbonated soda beverages, fruit juices, Jell-O, Kool-Aid, and tea are not suitable for use because they have inappropriately high osmolalities owing to excessive carbohydrate concentrations, which may exacerbate diarrhea; low sodium concentrations, which may cause hyponatremia; and inappropriate carbohydrate to sodium ratios. Once rehydration is complete, food should be reintroduced while the oral electrolyte solution is continued to replace ongoing losses from stools and for maintenance. Breast-feeding of infants should be resumed as soon as possible. Older children should be re-fed as soon as they can tolerate feeding. Foods with complex carbohydrates (e.g., rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruits, and vegetables are better tolerated. Fatty foods or foods high in simple sugars (including juices and carbonated sodas) should be avoided.

ANTIDIARRHEAL COMPOUNDS.

These agents are classified by their mechanism of action, which includes alteration of intestinal motility, adsorption of fluid or toxins, alteration of intestinal microflora, and alteration of fluid and electrolyte secretion. Antidiarrheal compounds generally are not recommended for use in children with diarrhea because of their minimal benefit and potential for side effects.

Prevention.

Patients who are hospitalized should be placed under contact precautions, including handwashing before and after patient contact, gowns when soiling is likely, and gloves when touching contaminated material. Patients and their families should be educated about the mode of acquisition of enteropathogens and methods to decrease transmission. Patients who attend childcare centers should be excluded from the center or cared for in a separate area until diarrhea has subsided. Cases of diarrhea caused by *C. botulinum, E. coli* O157:H7, *Salmonella, Shigella, V. cholerae, Cryptosporidium*, and *Cyclospora* are nationally notifiable diseases and should be reported to personnel at the local health department. Other enteric pathogens associated with outbreaks (e.g., in childcare centers) or food borne or water borne disease also should be reported.

Vaccines are available to prevent or modify infection by *Salmonella typhi* (see Chapter 181). A rotavirus vaccine was briefly available in the United States but has been removed from the market because of the association with intussusception. Other vaccines to prevent rotavirus infection are in clinical trials.

Acute Food Borne and Water Borne Disease.

Food borne and water borne disease is a major cause of morbidity and mortality in all developed countries, including the United States. Changes in food production, flaws in inspection systems, rapid international distribution of food, alterations in dietary habits, and lack of recognition of methods of prevention magnify these problems. Food borne illness in the United States is estimated to cause millions of cases of gastroenteritis yearly, which results in thousands of deaths and is associated with billions of dollars in medical costs and lost productivity.

The diagnosis of a food borne or water borne illness should be considered when two or more persons who have ingested common food or water develop a similar acute illness that usually is characterized by nausea, emesis, diarrhea, or neurologic symptoms. Pathogenesis and severity of bacterial disease depend on whether organisms have preformed toxins (e.g., *Staphylococcus aureus, Bacillus cereus*), produce toxins, or are invasive and whether they replicate in food. The severity of disease due to viral, parasitic, and chemical causes depends on the amount inoculated into the food or water, whereas bacteria have the potential to replicate in food once introduced. The epidemiology of outbreaks often suggests specific etiologic agents. Determination of the incubation period and the specific clinical syndrome often leads to the correct diagnosis. Confirmation is established by specific laboratory testing of food, stool, or emesis. As a general rule, when outbreaks are grouped by incubation period of illness, those occurring in less than

1?hr are associated with chemical poisoning, toxins from fish or shellfish, or preformed toxins of *S. aureus* or *B. cereus.* Enterotoxin-producing bacteria, invasive bacteria, calicivirus, and some forms of mushroom poisoning have longer incubation periods.

CLINICAL SYNDROMES.

Several clinical syndromes follow ingestion of contaminated food or water, including nausea and vomiting within 6?hr; paresthesia within 6?hr; neurologic and gastrointestinal tract symptoms within 2?hr; abdominal cramps and watery diarrhea within 16–48?hr; fever, abdominal cramps, and diarrhea within 8–72?hr; abdominal cramps and bloody diarrhea without fever within 72–120?hr; neurologic signs and symptoms within 6–24?hr; and nausea, vomiting, and paralysis within 18–48?hr (Table 321–4).

TABLE 321-4 -- **Clinical Manifestations, Incubation Periods, and Major Causes of Foodborne Diseaset**

Clinical Manifestations	Incubation Periods (hr)	Main Causative Agents
Gastrointestinal tract		
Vomiting	<1	Chemical
Vomiting and diarrhea	1–6	*Bacillus cereus* and *Staphylococcus aureus* preformed toxins
Watery diarrhea, abdominal cramps	8–72	Many organisms including *Salmonella*
Bloody diarrhea	=15	Many organisms including *Salmonella*
Neurologic	0–6	Fish, shellfish, monosodium glutamate
	0–24	Mushrooms
	18–24	*Clostridium botulinum*
Systemic	Varied	*Listeria monocytogenes* *Brucella* *Trichinella* *Toxoplasma gondii* *Vibrio vulnificus* Hepatitis A

Short incubation periods with vomiting as the major sign are associated with toxins that produce direct gastric irritation, such as heavy metals, or with preformed toxins of *B. cereus* or *S. aureus*; *B. cereus* also produces an enterotoxin. Paresthesias after a brief incubation period are suggestive of scombroid (histamine) fish poisoning, paralytic or neurotoxic shellfish poisoning, Chinese restaurant syndrome (monosodium glutamate poisoning), niacin poisoning, or ciguatera fish poisoning. The early-onset syndrome associated with ingestion of toxic mushrooms ranges from gastroenteritis to neurologic symptoms that include parasympathetic hyperactivity, confusion, visual disturbances, and hallucinations to hepatic or hepatorenal failure, which occurs after a 6–24?hr incubation period.

Watery diarrhea and abdominal cramps after an 8–16?hr incubation period are associated with enterotoxin-producing *Clostridium perfringens* and *B. cereus.* Abdominal cramps and watery diarrhea after a 16–48?hr incubation period can be associated with calicivirus, several enterotoxin-producing bacteria, *Cryptosporidium,* and *Cyclospora.* Several organisms including *Salmonella, Shigella, C. jejuni, Y. enterocolitica,* enteroinvasive *E. coli,* and *V. parahaemolyticus* are associated with diarrhea that may contain fecal leukocytes, abdominal cramps, and fever, although these organisms can cause watery diarrhea without fever. Bloody diarrhea and abdominal cramps after a 72–120?hr incubation period are associated with Shiga toxin–producing *E. coli,* such as *E. coli* O157:H7. Hemolytic-uremic syndrome (see Chapter 510) is a sequela of infection with Shiga toxin–producing *E. coli.* The combination of gastrointestinal tract symptoms followed by blurred vision, dry mouth, dysarthria, diplopia, or descending paralysis suggests *Clostridium botulinum*.

Therapy for most persons with food borne disease is supportive, because the majority of these illnesses are self-limited. Exceptions are botulism, paralytic shellfish poisoning, and long-acting mushroom poisoning, all of which may be fatal in previously healthy persons. If a food borne or water borne outbreak is suspected, public health officials should be notified.

Chapter 322 - Chronic Diarrhea

Fayez K. Ghishan

Diarrhea in children accounts for approximately 5 million deaths per year in the developing world (see Chapter 321). In the United States, diarrhea accounts for 10% of all outpatient visits and 14 hospital admissions each year per 1,000 children younger than 1 yr of age.

Definition.

Diarrhea, defined as increased total daily stool output, is usually associated with increased stool water content (see Chapter 287 and Chapter 321). For infants and children, this would result in stool output greater than 10?g/kg/24?hr or more than the adult limit of 200?g/24?hr. Diarrhea lasting longer than 2 wk is considered chronic. Diarrhea results from altered intestinal water and electrolyte transport. The gastrointestinal tract of the infant handles approximately 285?mL/kg/24?hr of fluid (intake plus intestinal secretion) with a stool output of 5–10?g/kg/24?hr. The efficient mechanisms responsible for this absorptive capacity are caused by the function of several transport proteins located at the brush border membrane of the small and large intestine. The transport of electrolytes across the gastrointestinal tract contributes to the overall absorptive process of the small and large intestine. The stool output in infants and children contains approximately, per liter, 20–25?mEq of sodium, 50–70?mEq of potassium, and 20–25?mEq of chloride. The normal cellular mechanisms responsible for the transport of nutrients and electrolytes across the gastrointestinal tract are noted in Figure 322–1 .

Functional Anatomy of the Intestinal Mucosa.

The villus, the functional unit of the small intestine, greatly amplifies the absorptive and digestive surface of the intestinal mucosa. The tip of the villus represents the highly differentiated absorptive cells, whereas the crypt epithelia represent undifferentiated secretory cells. The epithelial cells at the tip of the villus are continually renewed every 4–5 days from the undifferentiated crypt cells. Digestive enzymes and the transport proteins responsible for the movements of electrolytes across the intestinal mucosa are located at the brush border membrane of the villus cells. The gastrointestinal epithelia are leaky epithelia that adjust the osmotic load presented to the small intestine. Tight junctions, dynamic structures that occur between the epithelial cells, contribute to overall movement of water and electrolytes.

Transport of electrolytes across the intestinal epithelia occurs through several mechanisms, including the glucose-sodium co-transporter. This transport protein requires the presence of a sodium gradient across the brush border membrane that is maintained by the sodium-potassium adenosine triphosphatase (Na^+ , K^+ ATPase) pump at the basolateral membranes of the enterocyte. The defect in glucose-galactose malabsorption is a missense mutation in the sodium-glucose co-transporter gene (see Chapter 320.12).

A second mechanism of electrolyte transport across the intestinal epithelia is the electroneutral NaCl-coupled pathway that involves the double exchange mechanism by the Na^+ -H^+ exchanger and the Cl^- HCO_3^- exchanger. Two Na^+ -H^+ exchangers (NHE-2 and 3) located at the apical membrane appear to be involved in the transport of Na^+ . Defects of the genes of Na^+ -H^+ and Cl^- HCO_3^- exchangers are candidates for congenital Na^+ and Cl^- diarrhea, respectively. Na^+ is absorbed in the colon by the electroneutral NaCl-coupled pathway and by an electrogenic mechanism, which is regulated by aldosterone. Intestinal secretion occurs primarily from the crypt cells and is stimulated by an increase in the intracellular level cyclic adenosine

Figure 322-1 Normal transport of nutrients and electrolytes across the gastrointestinal (GI) tract of an infant. The GI tract of the infant handles 285?mL/kg/day of dietary and endogenous fluids. Most of the nutrients and fluids are absorbed by means of transport protein, depicted schematically. NHE-2 and NHE-3 indicate Na^+ /H^+ exchanger isoforms 2 and 3. The colon absorbs mainly water and electrolytes through the electroneutral NaCl and the electrogenic Na+ process.

monophosphate (AMP), cyclic guanosine monophosphate (GMP), and Ca^{2+} . These mediators inhibit the neutral NaCl entry and permit the entry of Cl^- into the cells through the basolateral membrane via the Na^+ -K^+ -2Cl^- transporter. Cl^- is then secreted through the opening of Cl^- channels at the apical membrane of the crypt cells. Na^+ and thus water secretion will result in secretory diarrhea. The Na^+ -glucose co-transporter is not altered by the intracellular mediators, and, thus, this concept forms the basis of oral rehydration solutions. Figure 322–2 depicts a model for intestinal secretion induced by enterotoxins.

Pathophysiology.

The pathophysiologic mechanisms of diarrhea include osmotic diarrhea, secretory diarrhea, mutations in apical membrane transport proteins, a reduction in anatomic surface area, and alteration in intestinal motility (see Table 287–4).

OSMOTIC DIARRHEA.

Osmotic diarrhea is caused by the presence of nonabsorbable solutes in the gastrointestinal tract (Box 322–1). The classic example of osmotic diarrhea is lactose intolerance caused by lactase enzyme deficiency in which lactose is not absorbed in the small intestine and reaches the colon intact (see Chapter 320.11). The colonic bacteria ferment the nonabsorbed lactose to short-chain organic acids, generating an osmotic load causing water to be secreted into the lumen. Other examples include ingestion of excessive amounts of sugar-containing carbonated fluids that exceed the transport capacity, especially in toddlers, and ingestion of magnesium salts and sorbitol; both are not absorbed, resulting in an osmotic load. Lactulose, a synthetic therapeutic disaccharide, is not digested in

Figure 322-2 Model for intestinal secretion: Enterotoxins increase intracellular mediators (cAMP, cGMP, Ca2+), which open chloride channels in the crypt cells and inhibit the neutral NaCl coupled pathway at the villus cells.

the small intestine and is fermented by the colonic bacteria to form organic acids resulting in osmotic diarrhea. Osmotic diarrhea stops with fasting, has a low pH, and is positive for reducing substances. The sum of sodium plus potassium multiplied by 2 in the stools will be less than the measured stool osmolarity, a finding suggesting the presence of other osmols in the stool. The main diagnostic points that differentiate osmotic from secretory diarrhea are noted in Table 322–1 .

SECRETORY DIARRHEA.

The major causes of secretory diarrhea are depicted in Box 322–2 . The mechanisms for secretory diarrhea include activation of the intracellular mediators such as cyclic AMP, cyclic GMP, and intracellular Ca^{2+} , which stimulate active Cl^- secretion from the crypt cells and inhibit the neutral coupled sodium chloride absorption. These mediators alter the paracellular ion flux because of toxin-mediated injury to the tight junctions. The classic example of secretory diarrhea is that induced by cholera and *Escherichia coli* enterotoxins that bind to a specific enterocyte surface receptor (the monosialoganglioside GM_1); a fragment of the toxin then enters the cell, where it activates adenylate cyclase on the basolateral membrane through interaction with a stimulatory G protein. This increases intracellular cyclic AMP. The enterotoxigenic *E. coli* mediates secretory diarrhea by producing heat-labile toxin (LT) and heat-stable toxin (ST) in the small bowel. The labile toxin is

Box 322-1. Causes of Osmotic Diarrhea

Malabsorption of water-soluble nutrients

Glucose-galactose malabsorption

- Congenital
- Acquired

Disaccharidase deficiencies (lactase and sucrase-isomaltase)

- Congenital
- Acquired

Excessive intake of carbonated fluids

Excessive intake of nonabsorbable solutes

- Sorbitol
- Lactulose
- Magnesium hydroxide

TABLE 322-1 -- **Differential Diagnosis of Osmotic versus Secretory Diarrhea**

	Osmotic Diarrhea	Secretory Diarrhea
Volume of stool	<200 mL/24 hr	>200 mL/24 hr
Response to fasting	Diarrhea stops	Diarrhea continues
Stool Na^+	<70 mEq/L	>70 mEq/L
Reducing substances*	Positive	Negative
Stool pH	<5	>6

**Sucrose is not a reducing agent. Add 5 drops of 0.1 N HCl to a stool sample before adding reducing agent (Clinitest tablet).*

similar in its action to the cholera toxin and binds to the same GM_1 surface receptor. Other causes of secretory diarrhea include vasoactive peptides, which activate G protein–coupled receptors resulting in an increase in intracellular mediators causing secretory diarrhea.

Secretory diarrhea is characterized by high volume; the stools are extremely watery. Stool analysis reveals high sodium and chloride content (>70?mEq/L). Secretory diarrhea continues with fasting.

MUTATIONAL DEFECTS IN ION TRANSPORT PROTEINS.

Congenital defects of Na^+ -H^+ exchange, Cl^- HCO_3^- exchange, and Na^+ -bile acid transport proteins result in secretory diarrhea presenting at birth (see Chapter 320.12). The defects in Cl^- HCO_3^- exchange and Na^+ -bile acid transporters have gene mutations that encode their corresponding transport proteins. The defect in Na^+ -H^+ exchange is believed to represent defects in the apical Na^+ -H^+ exchanger (NHE-2 or NHE-3). Patients with these defects present with secretory diarrhea and failure to thrive during the neonatal period. The defect in Cl^- HCO_3^- exchange is well characterized and is more common compared with the defects in Na^+ -H^+ exchange and Na^+ -bile acid transporter (see Chapter 320.2). Patients with Cl^- diarrhea have hypochloremic metabolic alkalosis with low serum Cl^- concentration, high stool Cl^- content coupled with Cl–free urine, low serum K^+ , and high serum HCO_3^- . Hydramnios is present in the mothers.

REDUCTION IN ANATOMIC SURFACE AREA.

Short bowel syndrome results from resection of the bowel secondary to surgical indications such as necrotizing enterocolitis, midgut volvulus, or intestinal atresia (see Chapter 320.7). Celiac disease results in flattening of the proximal intestinal surface area with marked decrease in the digestive and absorptive function of the villus epithelium (see Chapter 320.8). Diarrhea is characterized by loss of fluids, electrolytes, macronutrients, and micronutrients.

ALTERATION IN INTESTINAL MOTILITY.

The causes of altered intestinal motility include malnutrition, scleroderma, intestinal pseudo-obstruction syndromes, and diabetes mellitus. Malnutrition, in general, results in hypomotility, allowing bacterial overgrowth that leads to deconjugation of bile salts and

Box 322-2. Causes of Secretory Diarrhea

Activation of cyclic adenosine monophosphate

- Bacterial toxins: enterotoxins of cholera, *Escherichia coli* (heat-labile), *Shigella, Salmonella, Campylobacter jejuni, Pseudomonas aeruginosa*
- Hormones: vasoactive intestinal peptide, gastrin, secretin
- Anion surfactants: bile acids, ricinoleic acid

Activation of cyclic guanosine monophosphate

- Bacterial toxins: *E. coli* (heat-stable) enterotoxin, *Yersinia enterocolitica* toxin

Calcium-dependent

- Bacterial toxins: *Clostridium difficile* enterotoxin
- Neurotransmitters: acetylcholine, serotonin
- Paracrine agents: bradykinin

results in an increase in the intracellular mediator cyclic AMP, leading to secretory diarrhea.

Etiology.

A simple classification for the etiology of chronic diarrhea is shown in Table 322–2 . The two major factors resulting in diarrhea include intraluminal factors and mucosal factors. Intraluminal factors are involved in the digestion process, whereas mucosal factors are involved in the digestion and transport of nutrients across the mucosa. In many situations, both intraluminal and mucosal factors cause diarrhea. The intraluminal factors involve disorders of the pancreas, liver, and the brush border membrane of the enterocytes. In approximately 85% of patients with cystic fibrosis, pancreatic insufficiency results in malabsorption of fats and proteins. Short stature, exocrine pancreatic hypoplasia, normal sweat Cl^- concentrations, and the variable features of neutropenia and skeletal changes characterize *Shwachman syndrome* (see Chapter 330). *Johannson-Blizzard syndrome* is characterized by anal imperforation, agenesis of the nasal cartilage, hair anomalies, mental retardation, deafness,

TABLE 322-2 -- Etiology of Chronic Diarrhea

INTRALUMINAL FACTORS	MUCOSAL FACTORS
Pancreatic Disorders	***Altered Integrity***
Cystic fibrosis	Infections: bacterial, viral, fungal
Shwachman-Diamond syndrome	Infestations: parasitic
Johannson-Blizzard syndrome	Cow's and soy protein intolerance
Isolated pancreatic enzyme deficiencies	Inflammatory bowel disease (ulcerative colitis, microscopic colitis, Crohn)
Chronic pancreatitis	
Pearson syndrome	
Bile Acid Disorders	***Altered Immune Function***
Chronic cholestasis	Autoimmune enteropathy
Terminal ileum resection	Eosinophilic gastroenteropathy
Bacterial overgrowth	AIDS
Chronic use of bile acid sequestrants	Combined immunodeficiency
Primary bile acid malabsorption	Immunoglobulin A and G deficiencies
Intestinal Disorders	***Altered Function***
Intraluminal osmolarity	Defects in Cl^- /HCO_3^- , Na^+ /H^+ , bile acids, acrodermatitis enteropathica, selective folate deficiency, abetalipoproteinemia

Carbohydrate malabsorption	
Congenital and acquired sucrase, lactase deficiencies	
Congenital and acquired monosaccharide malabsorption	
Excessive carbonated fluid intake	
Excessive intake of sorbitol, Mg $(OH)_2$ and lactulose	
	Altered Digestive Function
	Enterokinase deficiency
	Glucoamylase deficiency

	Celiac disease
	Postgastroenteritis syndrome
	Microvillus inclusion disease
	Short bowel syndrome
	Altered Secretory Function
	Enterotoxin-producing bacteria
	Tumors secreting vasoactive peptides
	Altered Anatomic Structures
	Hirschsprung disease
	Partial small bowel obstruction
	Malrotation

hypothyroidism, and pancreatic insufficiency (see Chapter 330). The isolated pancreatic enzyme defects are congenital and result in malabsorption of fat or proteins, depending on the defect. These defects include congenital lipase/colipase deficiency and congenital trypsinogen deficiency. Patients with chronic pancreatitis can present with pancreatic insufficiency and insulin-dependent diabetes. Familial pancreatitis, secondary to a mutation in the trypsinogen gene, can result in chronic pancreatitis and pancreatic insufficiency. *Pearson syndrome* is characterized by refractory sideroblastic anemia with vacuolization of bone marrow precursors, exocrine pancreatic insufficiency, and mitochondrial DNA deletions and duplications. Disorders of the liver, such as cholestasis, result in a decrease in bile acid pool size with malabsorption of fats. Bile acid loss with fat malabsorption can occur with terminal ileum disease such as Crohn disease or with terminal ileum resection. Primary bile acid malabsorption is a rare disorder secondary to a mutation in the ileal bile acid transporter. Patients present with fat malabsorption and diarrhea. Bacterial overgrowth in the gastrointestinal tract results in deconjugation and dehydroxylation of bile salts, resulting in diarrhea. Long-term use of bile acid sequestrants such as cholestyramine can lead to a decrease in bile acid pool size because of the continued loss of bile acids in the stools. Intraluminal osmolarity, resulting from malabsorption of carbohydrates, presents as an osmotic type of diarrhea. The causes of carbohydrate malabsorption include congenital and acquired causes of monosaccharide and disaccharidase deficiencies. Excessive sugar-containing carbonated fluid or fruit juice intake, which exceeds the transport capacity of the small intestine in younger infants, results in *nonspecific diarrhea*. Excessive intake of nonabsorbable solutes such as sorbitol, magnesium hydroxide, and lactulose results in osmotic diarrhea.

The mucosal factors that lead to chronic diarrhea could be secondary to altered mucosal integrity from infections such as bacterial, viral, parasitic, and fungal agents. Parasitic infestations such as with *Giardia* or cryptosporidia can present as chronic diarrhea. Inflammatory bowel disease such as ulcerative colitis, Crohn disease, and microscopic colitis can lead to the alteration in the mucosal integrity resulting in the decreased absorption of water electrolyte through the gastrointestinal tract. Cow's milk and soy protein intolerance can present with diarrhea secondary to partial villus atrophy or allergic colitis. Altered immune function as seen in patients with agammaglobulinemia, isolated immunoglobulin A deficiency, and combined immunodeficiency disorders can result in diarrhea. Patients with AIDS are more predisposed to bacterial, viral, and fungal infections. Similarly, autoimmune enteropathy and eosinophilic gastroenteropathy are believed to be disorders involving alteration of the mucosal immune function and can result in diarrhea. Altered mucosal transport function, as seen in congenital disorders involving Na^+ -H^+ exchange, Cl^- HCO_3^- exchange, bile acid transport, and glucose-galactose transport, results in diarrhea early in the neonatal period. Similarly, defects in the absorption of zinc, such as acrodermatitis enteropathica and folate transport, can result in diarrhea.

Abetalipoproteinemia is characterized by fat malabsorption, neurologic lesions, and ocular abnormalities such as retinitis pigmentosa (see Chapter 75.3). The diagnosis is confirmed by the typical hematologic finding of acanthocytosis and the appearance

of the small bowel biopsy specimen in which the tip enterocytes are filled with lipid droplets. Altered mucosal digestive function includes congenital enterokinase deficiency that results in loss of activation of trypsinogen to trypsin with protein malabsorption (see Chapter 322.11). Glucoamylase deficiency is rare and results in loss of hydrolysis of glucose polymers.

Altered mucosal surface area is seen in celiac disease, partial villus atrophy secondary to postgastroenteritis malabsorption syndrome, tropical sprue, microvillus inclusion disease, Whipple disease, and short bowel syndrome. In these disorders, the height and structure of the villi are altered so that the absorptive capacity of the mucosal surface area is markedly decreased. Celiac disease occurs secondary to gluten sensitivity (see Chapter 320.8). Postgastroenteritis syndrome is a nutritional disorder that occurs after a prolonged episode of gastroenteritis and decreased energy intake. Microvillus inclusion disease is characterized with diarrhea, failure to thrive, and histologic picture of microvillus inclusions (see Chapter 320). The mucosal surface lacks brush border membranes or possesses irregular blunted microvilli. Whipple disease is mainly seen in adults and is secondary to an actinomycete, *Tropheryma whippelii.* Patients present with weight loss, diarrhea, and arthropathy. The diagnosis is established by a small bowel biopsy, and patients respond to prolonged administration of trimethoprim-sulfamethoxazole. Tropical sprue is commonly seen in patients living or returning from trips to developing countries (see Chapter 320.4). Patients present with diarrhea and nutritional deficiencies, especially of folate. Alteration in the anatomic structure as seen in Hirschsprung disease, malrotation, and partial small bowel obstruction can result in diarrhea secondary to bacterial overgrowth. Altered mucosal secretory function includes enterotoxin-producing bacteria and tumor-secreting vasoactive peptides. Box 322–3 summarizes the most common causes of chronic diarrhea at various ages.

Evaluation.

The evaluation of patients with chronic diarrhea is depicted in Box 322–4 . It is important to determine that the patient indeed has diarrhea, because patients with encopresis may be mistakenly considered to have diarrhea secondary to constant fecal soiling. In phase I, the history and physical examination, which includes a nutritional assessment, is the initial step. The clinical history should include the amount and type of fluids ingested per day. If the patient's clinical history suggests excessive carbonated drinks or fruit juices of more than 150?mL/kg/24?hr, with normal growth and height parameters, chronic nonspecific diarrhea needs to be considered. A decrease in the amount of fluid to no more than 90?mL/kg/24?hr will result in resolution of the diarrhea. If the patient is ingesting nonabsorbable nutrients in excessive amounts such as sorbitol, a dietary adjustment needs to be made before extensively investigating the patient.

The stool examination is an integral step in investigating a patient with chronic diarrhea. The most recently evacuated stool, including its liquid content, is useful for diagnostic purposes. Various collection techniques are helpful, including the placement of a urine collection bag over the anus and everting a disposable diaper to collect the stool. Once collected, the stool specimen should be stored in a refrigerator until the examination is performed. Specimens for bacterial culture should

Box 322-4. Evaluation of Patients with Chronic Diarrhea

PHASE I	Clinical history including specific amounts of fluids ingested per day Physical examination including nutritional assessment Stool exam (pH, reducing substances, smear for white blood cell count, fat, ova, and parasites) Stool cultures Stool for *Clostridium difficile* toxin Blood studies (complete blood cell count, erythrocyte sedimentation rate, electrolytes, blood urea nitrogen, creatinine)
PHASE II	Sweat chloride 72-Hr stool collection for fat determination Stool electrolytes, osmolality Stool for phenolphthalein, magnesium sulfate, phosphate Breath H_2 tests
PHASE III	Endoscopic studies Small bowel biopsy Sigmoidoscopy or colonoscopy with biopsies Barium studies
PHASE IV	Hormonal studies vasoactive intestinal polypeptide, gastrin, secretin, 5-hydroxyindoleacetic assays

be transported immediately to the bacteriology laboratory for inoculation into growth media. The gross examination of the stool should allow the physician to determine whether the patient has diarrhea and whether blood or mucus is present in the stool, a finding suggesting inflammation of the colon. The

Figure 322-3 General therapeutic approaches to management of chronic diarrhea.

color of the stool is rarely helpful unless it is bloody. Occult testing for blood is useful to determine whether the patient has microscopic blood loss. Carbohydrate malabsorption is detected by analysis of the liquid fraction of a fresh specimen. A pH lower than 5 or the presence of moderate reducing substances indicates the presence of reducing carbohydrates (sucrose is not a direct reducing substance). The stools should be sent for electrolytes and osmolality testing if secretory diarrhea is considered (see Table 322–1).

Microscopic examination of the stool helps to determine the presence of white blood cells, which signifies colonic inflammation. The stools could be examined for ova and parasites such as *Giardia,* amebae, or cryptosporidia. Trichrome stain or acid-fast stain can be of value in identifying *Cryptosporidium* species. Stools should be examined for the presence of *Giardia* antigen. Sudan stain can be used either on a plain stool smear or with the addition of acetic acid and heat to determine the presence of triglycerides and split fats.

In the event that phase I investigation has failed to reveal a cause, a phase II work-up is indicated and includes a sweat chloride test to rule out cystic fibrosis. A 72-hr stool collection for fat determination is the standard to determine whether the patient does have fat malabsorption in the setting of a negative sweat chloride test. Stools could also be checked for phenolphthalein, magnesium sulfate, and phosphate to determine whether the diarrhea is secondary to the ingestion of laxatives *(factitious diarrhea).* Breath hydrogen tests can be used to determine a specific carbohydrate malabsorption. A breath hydrogen test for glucose can be used to diagnose bacterial overgrowth.

Phase III investigation includes endoscopic studies for small bowel and colonic biopsies. Barium studies, such an upper gastrointestinal series or a barium enema, can be used to rule out anatomic lesions in the gastrointestinal tract. If none of these tests is revealing, phase IV evaluation includes hormonal studies and neurohormonal and neurotransmittal studies such as vasoactive intestinal polypeptide, gastrin,

secretin, and 5-hydroxyindoleacetic assays.

Treatment.

Figure 322–3 depicts the general therapeutic approaches to the management of chronic diarrhea. The first principle is to maintain adequate nutritional intake to permit normal growth and development. The height, weight, and nutritional status of the patient must be documented. If nutritional parameters, including weight and height, are normal and the stool examination does not show any fat, the possibility of chronic nonspecific diarrhea needs to be considered. The pathogenesis of this condition includes excessive carbonated fluid intake, nondigestible carbohydrate malabsorption from excessive fruit juice ingestion, and low fat intake.

Chronic nonspecific diarrhea generally presents in well-appearing toddlers between 1 and 3 yr (toddler's diarrhea). The diarrhea is often brown and watery, at times containing undigested food particles. If the child's fluid intake is more than 150?mL/kg/24?hr, fluid intake should be reduced to no more than 90?mL/kg/24?hr. Parents may note that the child is irritable in the first 2 days after the fluid restriction; however, persistence in this approach for several more days results in a decrease in the stool frequency and volume. If the dietary history suggests that the child is ingesting significant amounts of fruit juices, then the offending juices should be decreased. Sorbitol, which is a nonabsorbable sugar, is found in apple, pear, and prune juices and can cause diarrhea in toddlers. Moreover, apple and pear juices contain higher amounts of fructose in excess of glucose concentration, a feature postulated to cause diarrhea in toddlers. White grape juice is the best alternative.

Levels of dietary fat intake may also play a role in chronic diarrhea. If the child's fat intake has been restricted by the parents, then fat intake can be increased to be approximately 40% of the total calories per day.

If the diarrhea is secondary to carbohydrate intolerance, then a trial period of decreased lactose or sucrose may be initiated. Lactase (LactAid) can be used to aid in the digestion of lactose. If diarrhea persists, a trial of a lactose-free or sucrose-free diet is indicated. Alternatively, breath hydrogen tests can document the presence of lactose or sucrose intolerance. A glucose breath hydrogen test can be used for the diagnosis of bacterial overgrowth.

If the patient presents with weight loss and the stool examination shows fat, the possibility of chronic diarrhea secondary to a malabsorption syndrome needs to be considered. The most common cause of chronic diarrhea associated with the malabsorption is postgastroenteritis malabsorption syndrome. These patients respond well to a predigested formula. In the event that the patient shows intolerance to oral feeding with a predigested formula, such as Pregestimil or Alimentum, nasogastric drip-feeding with an elemental formula should be considered for a period of 3–4 wk.

A patient presenting with suspected small intestinal bacterial overgrowth should undergo evaluation for surgical, medical, and nutritional support. Surgical treatment is indicated if the patient has malrotation or partial small bowel obstruction. Antibiotic therapy is usually initiated with metronidazole in combination with ampicillin or trimethoprim-sulfamethoxazole.

Patients presenting with secretory diarrhea, especially during the 1st mo of life, need to be considered for nutritional support, because the most likely cause is a congenital defect in transport proteins. In older children with secretory diarrhea, the cause needs to be identified first, and therapeutic consideration is directed toward the cause of the secretory diarrhea.

Chapter 323 - Recurrent Abdominal Pain of Childhood

Robert Wyllie

Chronic abdominal pain can be classified as either organic or nonorganic depending on whether a specific cause of the pain is identified. Nonorganic pain or “functional” abdominal pain refers to pain that cannot be explained on a structural or biochemical basis. Recurrent abdominal pain (RAP) in children is defined as episodes of pain occurring at least monthly for 3 consecutive months with a severity that interrupts routine functioning. RAP affects about 15% of middle and high school students. Approximately 10% of students who experience abdominal pain seek medical evaluation. The likelihood of seeking medical attention is proportional to the severity and frequency of abdominal pain and its impact on school attendance.

Early investigators found an organic cause for RAP in 5–10% of children. With advancement in medical technology, including endoscopic techniques, breath hydrogen testing, and radiographic analysis, the percentage of patients with unexplained pain is decreasing. However, for the majority of teenagers with RAP no specific cause can be found with current diagnostic techniques.

Periumbilical abdominal pain is the most common location for children with RAP. Epigastric pain is frequently associated with symptoms of early satiety, nausea, bloating, or belching and, in the presence of a negative evaluation and no response to acid-blocking medication, is referred to as nonulcer dyspepsia. Pain below the umbilicus is often accompanied by abdominal cramps, bloating, and distention with an altered bowel pattern. This complex of symptoms is consistent with irritable bowel syndrome (IBS) in the adult population. IBS-type symptoms have been documented in about one third of the children with RAP. Gastrointestinal tract symptoms are positively related to both anxiety and depression, particularly in children with IBS-type symptoms. Improvement in symptoms during weekends and school vacations suggests functional pain, but the absence of this pattern does not rule out this diagnosis.

Investigations into the etiology of RAP have focused on the autonomic nervous system and intestinal motility abnormalities. The dorsal horn of the spinal cord regulates conduction of impulses from peripheral nociceptive receptors to the spinal

cord and brain, and the pain experience is further influenced by cognitive and emotional centers. Chronic peripheral pain can produce increased neural activity in higher central nervous system centers, leading to perpetuation of pain. Psychosocial stress can affect pain intensity and quality through these mechanisms. Manometric studies suggest altered motility in combination with heightened awareness in certain children may cause abdominal pain. Differences in visceral sensation may lead to differences in perception of pain.

The child's response to pain can be influenced by stress, by personality type, and by the reinforcement of illness behavior within the family. A significantly higher proportion of children with RAP have relatives with somatization disorders, alcoholism, and antisocial behavior problems. Parents and siblings are more likely to have complaints of abdominal pain, nervous breakdown, and migraine headaches. Children with functional abdominal pain are more likely to experience stressors. Sexual abuse as a child may be associated with RAP. This possibility should always be considered, especially in a girl whose abdominal symptoms begin in the pre-teenage or teenage years.

Diagnosis.

A wide range of potential organic causes of RAP (see Table 287–4) must be considered before establishing a diagnosis of functional pain. Among the more common causes are chronic constipation, parasitic infection (*Giardia*), gastroesophageal reflux, and lactase deficiency. Lactose intolerance is so common that the finding may be coincidental; therefore, one must be cautious in attributing chronic abdominal pain to this condition. Pinworms are unlikely to be the cause of abdominal pain.

The characteristic presentation of children with RAP includes onset later than 6 yr of age and midline paroxysmal pain, most often periumbilical but also localized to the epigastric or suprapubic area. The pain interrupts normal activity, but there is usually no relationship with meals. Children with IBS typically have abdominal pain relieved by defecation. They may notice mucus in their stools and looser or more frequent stools at the outset of their pain. Bloating or the sense of incomplete evacuation may also be present.

Symptoms suggestive of an organic etiology include age younger than 6 yr, fever, weight loss, joint symptoms, or abnormal growth. Organic pain is usually localized away from the umbilicus and may wake the patient from sleep. Vomiting, diarrhea, and blood in the stool are more suggestive of an organic etiology. Children with RAP have a normal physical examination, whereas those with organic etiology may have fissures or evidence of occult blood in the stool. Serial growth points should be plotted if available because growth deceleration is frequently associated with organic causes of abdominal pain.

Evaluation.

The laboratory, radiologic, or endoscopic evaluation of children with chronic

abdominal pain should be individualized, depending on the findings suggested by a detailed history and physical examination. Laboratory studies may be unnecessary if the history and physical examination clearly lead to a diagnosis of functional abdominal pain. However, a complete blood cell count, sedimentation rate, stool test for parasites (especially *Giardia*), and urinalysis are reasonable screening studies. If inflammatory bowel disease is suspected the sedimentation rate is often elevated. The finding of an abnormal sedimentation rate would make one look further for an inflammatory, infectious, or neoplastic disorder. If indicated, an ultrasound examination of the abdomen can give information about kidneys, gallbladder, and pancreas; with lower abdominal pain, a pelvic ultrasonogram may be indicated. An upper gastrointestinal tract x-ray series is indicated if one suspects a disorder of the stomach or small intestine. *Helicobacter pylori* infection does not seem to be associated with RAP. In patients with symptoms suggestive of gastritis or ulcer an *H. pylori* test (serum or fecal) may be performed to document the infection. Esophagogastroduodenoscopy is indicated with symptoms suggestive of persistent upper gastrointestinal pathology. In the absence of this suspicion, esophagogastroduodenoscopy is unlikely to identify an abnormality and is usually not necessary.

Treatment.

The family and the child with functional RAP may worry about the inability to identify an organic cause and may be resistant to a diagnosis of nonorganic disease. After a thorough history and physical examination the most important component of the treatment is reassurance of the children and family members. Specifically, they need to be reassured that no evidence of a serious underlying disorder is present. Cancer is often an unspoken concern. Anxiety about the symptom may contribute to focusing on the symptom as well as to reducing the threshold for discomfort. The parents should be instructed to avoid reinforcing the symptom with secondary gain. Furthermore, if children have missed school or have been removed from routine activities because of the pain, it is important that they return to regular activities. Medications are generally unhelpful or, at best, offer transient placebo effect. Gastric acid blockers or visceral muscle relaxants (anticholinergics) may be tried empirically, but they are most often not helpful in the absence of specific indication. Biofeedback and relaxation techniques have been useful in some children with functional pain.

If lactose intolerance is suspected, the diagnosis can be documented by breath hydrogen testing. Institution of a lactose-free diet usually results in resolution of the pain. Symptoms of gastroesophageal reflux will generally subside with the use of acid blockers. Recurrent symptoms are usually an indication for formal testing before instituting chronic therapy. Children with symptoms of irritable bowel and loose stools will often benefit from fiber supplementation. Anticholinergics or tricyclic antidepressants may be useful in some patients. If chronic constipation is identified, it should be treated in the standard fashion (see Chapter 20.4 and Chapter 313).

Successful management depends on close follow-up. The parents can try new approaches to the child's symptoms without fear that the physician is abandoning them if they know that follow-up by telephone or office visit has been arranged. Often it is during the follow-up visits that one truly comes to know the child and understand the symptoms. It is possible that an organic problem may not have been apparent on the initial visit but, with time, the symptom-complex becomes more typical. Adult patients with irritable bowel disease and constipation have been treated with tegaserod, whereas those with diarrhea have been treated with alosetron. The latter drug has serious complications; there is little experience with its use in children.

These approaches often result in reduction or elimination of the abdominal symptoms. However, children with functional abdominal pain are likely to become adults with functional disorders, although the nature of the symptoms may change.

Chapter 324 - Acute Appendicitis

Gary E. Hartman

Acute appendicitis is the most common condition requiring emergency abdominal operation in childhood. Diagnosis is difficult in young children, a factor contributing to perforation rates of 30–60%. Fifty per cent of children with perforated appendicitis have been seen by a physician before the diagnosis. The risk of perforation is greatest in 1- to 4-yr-old children (70–75%) and is lowest in the adolescent age group (30–40%), which has the highest age-specific incidence of appendicitis in childhood. The difficulty in distinguishing appendicitis from other common causes of abdominal pain and the increase in morbidity and mortality accompanying perforation keep appendicitis an important concern of clinicians.

Epidemiology.

Approximately 80,000 children experience appendicitis in the United States annually, a rate of 4/1,000 children younger than age 14 yr. Appendicitis is rare in developing countries, where diets are high in fiber. However, no causal relationship has been established between lack of dietary fiber and appendicitis. The incidence of appendicitis increases with age, peaking in adolescence and rarely occurring in children younger than 1 yr old. A familial predilection to appendicitis has been reported. Cases occur more often in males, clustering of cases has occurred, and cases occur more often in the autumn and spring.

Etiology.

Experimentally, ligation (obstruction) of the appendix results in a marked increase of intraluminal pressure, which rapidly exceeds systolic blood pressure. Initial venous congestion progresses to thrombosis, necrosis, and perforation. Clinically, obstruction of the lumen is the prime cause of appendicitis. The obstruction is caused by inspissated fecal material (fecalith). The inspissated material may calcify, leading to a radiographically visible appendicolith (15–20%). Obstruction resulting from mucosal edema may be associated with systemic or enteric viral or bacterial *(Yersinia, Salmonella, Shigella)* infections. Abnormal mucus has been suggested as the cause of the increased incidence of appendicitis in children with cystic fibrosis. Carcinoid tumors, foreign bodies, and *Ascaris* have rarely been implicated as causes of appendicitis. Neuroproliferation of the appendix may explain some instances of right lower quadrant pain that resolves with appendectomy, although no inflammation

of the appendix is identifiable grossly at operation or on routine pathologic examination.

Pathology.

The pathologic changes in appendicitis progress through three predictable phases. Initially, with luminal obstruction, venous congestion progresses to mucosal ischemia, necrosis, and ulceration. Bacterial invasion with inflammatory infiltrate through all layers of the appendiceal wall characterizes the second phase. Organisms can be cultured from the serosal surface before microscopic perforation. Finally, necrosis of the wall results in perforation and contamination of the peritoneum. The perforation usually occurs at the tip of the appendix, distal to the obstructing fecalith.

Subsequent to perforation, the microbiologic fecal contamination may be confined to the pelvis or the right iliac fossa by the omentum and adjacent loops of small bowel, or it may spread throughout the peritoneal cavity. Young children have a poorly developed omentum, and local perforation is not usually confined. Bacterial invasion of the mesenteric veins may result in portal vein sepsis (pylephlebitis) and subsequent liver abscess formation. The inflammatory process associated with perforation may lead to intestinal obstruction or paralytic ileus.

Clinical Manifestations.

The clinical signs and symptoms depend on the pathologic phase of appendicitis at examination. The classic triad consists of pain, nausea with vomiting, and fever. In the initial stage of appendiceal obstruction, the pain is periumbilical. Emesis usually follows the onset of pain and is infrequent. Anorexia is more common. Fever is low grade unless perforation with peritonitis has occurred. The sequence of symptoms with pain preceding emesis and fever is important in distinguishing appendicitis from infectious enteritis, which usually begins with vomiting followed by the cramping pain of hyperperistalsis. Diarrhea, if it occurs, is infrequent and consists of small, mucous stools caused by irritation of the sigmoid colon. Similarly, irritation of the bladder may produce urinary symptoms such as frequency and urgency.

As the inflammation progresses to involve the serosa and overlying peritoneum, the pain migrates to the area of peritoneal irritation, usually the right lower quadrant. If the appendix is retrocecal, the pain will be lateral or posterior and may mimic the symptoms associated with septic arthritis of the hip or psoas abscess. With perforation, the pain becomes generalized unless the contamination is well localized to produce a discrete abscess, usually of the right lower quadrant. Palpation of an abdominal or rectal mass indicates abscess formation.

The progression from onset of symptoms to perforation usually occurs over 36–48?hr. If the diagnosis is delayed beyond 36–48?hr, the perforation rate exceeds 65%.

Diagnosis

PHYSICAL EXAMINATION.

History and physical examination should be directed at establishing findings consistent with appendicitis and excluding alternative diagnoses such as viral gastroenteritis, constipation, urinary tract infection, hemolytic-uremic syndrome, Henoch-Schönlein purpura, mesenteric adenitis, pelvic osteomyelitis, psoas abscess, and tubo-ovarian diseases (ectopic pregnancy, ovarian cyst, pelvic inflammatory disease, ovarian torsion).

Pertinent aspects of the history favoring a diagnosis of appendicitis include onset of pain before vomiting or diarrhea, loss of appetite, migration of pain from periumbilical to right lower quadrant, and aggravation of pain during the trip to office or hospital. In excluding alternative diagnoses, it is essential to question the history of constipation, urinary tract symptoms, cough and fever suggesting lower lobe pneumonia, profuse diarrhea, headache, myalgias or other constitutional symptoms of viral syndromes, and similar symptoms in other household members. Untreated appendicitis proceeds to perforation within 48–72?hr; therefore, duration of symptoms is important in the interpretation of physical findings and in the determination of a treatment strategy.

Physical examination should begin with inspection of the child's demeanor as well as the appearance of the abdomen. The child with appendicitis frequently moves tentatively and slowly, hunched forward, and often with a slight limp. The child may protect the right lower quadrant with a hand and may be reluctant to climb onto the examining table. Early in appendicitis, the abdomen is flat. Discoloration or bruises should suggest abdominal trauma. Abdominal distention indicates a complication such as perforation or obstruction. Auscultation may reveal normal or hyperactive bowel sounds in early appendicitis, to be replaced with hypoactive bowel sounds as it progresses to perforation. Severe gastroenteritis usually produces persistently hyperactive bowel sounds.

Palpation of the abdomen should be gentle after the establishment of rapport and is aided by distraction with conversation or the assistance of a parent. The right lower quadrant (McBurney point) should be palpated last, after the examiner has had an opportunity to judge the response to examination of quadrants that should not be painful. The McBurney point is the junction of the lateral and middle thirds of the line joining the right anterior-superior iliac spine and the umbilicus. The most important physical finding in appendicitis is persistent direct tenderness to palpation and rigidity of the overlying rectus muscle. If the child is apprehensive or agitated from prior examination, the abdominal muscles may be diffusely tense, making interpretation of this finding impossible.

Testing for rebound tenderness must be done carefully to be meaningful. Deep abdominal palpation with sudden withdrawal of the examining hand causes pain or fear in all children and is not recommended. Gentle finger percussion in all four quadrants is a better test of rebound peritoneal irritation in all age groups but particularly in the frightened child. Testing for rebound tenderness and rectal examination should be the final aspects of the abdominal examination. The value of

rectal examination in the diagnosis of appendicitis has been questioned. If the history and abdominal examination are convincing for appendicitis, the rectal examination adds little information. However, if the diagnosis is in doubt, particularly in the very young (younger than 4 yr) or in the female adolescent, rectal examination often yields important information.

After the focused abdominal examination, careful examination of the other body regions, including ears, mucous membranes, lungs, and skin, for signs of other diseases should be noted. Careful attention should be made to identify shock from sepsis, dehydration, or both.

LABORATORY FINDINGS.

Laboratory evaluation of children with suspected appendicitis usually consists of complete blood cell count and urinalysis. Although many children with appendicitis have leukocytosis or shift in differential, many do not. The primary role of laboratory studies is to exclude alternative diagnoses such as urinary tract infection, hemolytic-uremic syndrome, Henoch-Schönlein purpura, and so on. The proximity of the appendix to the ureter may result in inflammatory cells in the urine. Up to 30 white blood cells per high-power field and 20 red blood cells have been reported in suppurative appendicitis. The presence of bacteria or pyuria greater than 30 white blood cells per high-power field suggests true urinary tract infection. Similarly, the presence of significant proteinuria or cast formation argues against appendicitis. Review of the complete blood cell count is directed at identification of microangiopathic anemia, thrombocytosis, or thrombocytopenia, all suggesting diagnoses other than appendicitis.

IMAGING STUDIES.

The imaging studies that may be helpful in evaluating children with suspected appendicitis include plain radiographs of the abdomen or chest, ultrasonography, CT, and rarely barium enema. Findings of appendicitis on abdominal films include calcified appendicolith, small bowel distention or obstruction, and soft tissue mass effect. Severe constipation or lower lobe pneumonia may establish an alternative diagnosis. Graded compression ultrasonography is a noninvasive study with false-negative and false-positive rates of 8–10% (Fig. 324–1). It is particularly helpful in adolescent girls, whose symptoms may be due to pelvic inflammatory disease, ovarian cysts, or torsion. CT of the abdomen and pelvis has been used for complicated perforation with intra-abdominal abscesses but now is the standard for early diagnostic imaging. Early CT can improve diagnostic accuracy and can reduce hospitalization in patients with a normal scan. CT is more sensitive and specific than ultrasonography and more likely to change patient management. The value of CT in the diagnosis, localization, and percutaneous drainage of abscesses occurring in the postoperative period is well established. Barium enema findings are those of

Figure 324-1 Graded compression ultrasonogram of acute appendicitis demonstrating edematous enlarged appendix compressed between the abdominal wall and the psoas muscle. int obl, internal oblique muscle; tr abd, transverse abdominis muscle; a, right iliac artery; v, right iliac vein. (From Puylaert JB, Rutgers PH, Laisang RI, et al: A prospective study of ultrasonography in the diagnosis of appendicitis. *N Engl J Med* 1987;317: 666.)

mass effect on the cecum from the inflammatory process and nonfilling or partial filling of the appendiceal lumen. However, many healthy children have nonfilling of the appendix, and this finding must be interpreted with caution.

DIFFERENTIAL DIAGNOSIS.

Accurate diagnosis of children with abdominal pain is facilitated by a thorough and systematic approach. At the conclusion of the history, physical examination, and initial laboratory studies (complete blood cell count, urinalysis), patients fall into three groups: those with definite or highly likely appendicitis, those with a definite alternate diagnosis, and those in whom the diagnosis remains uncertain.

Vomiting preceding the pain, large-volume diarrhea, and high fever suggest gastroenteritis caused by viral or bacterial (*Yersinia, Campylobacter*) agents. Localized right lower quadrant pain in this setting may be mesenteric adenitis. An abnormal hemogram combined with hemorrhagic skin lesions suggests Henoch-Schönlein purpura or hemolytic-uremic syndrome if renal function and findings of urinalysis are abnormal. Weight loss and prolonged symptoms, especially in a teenager, makes inflammatory bowel disease a serious consideration. Torsion of an undescended testis is common, and particular note should be made of testicular location. Follicular cysts of the ovary occur in midcycle and may be painful as a result of rupture, rapid enlargement, or hemorrhage. In pelvic inflammatory disease, the pain is usually suprapubic, bilateral, and of longer duration.

Children with cystic fibrosis have a high incidence of appendicitis, but they also have a high incidence of intussusception, constipation, and meconium ileus equivalent. Children with malignancies may experience abdominal pain as a result of their chemotherapy, constipation, typhlitis, or appendicitis. If their malignancy is in remission, the signs and symptoms of appendicitis should be the same as those for healthy children. If the malignancy is not controlled, typhlitis is likely if the child is neutropenic. This entity results from necrotizing enterocolitis

involving the terminal ileum and cecum and usually resolves with recovery of the neutrophil count and conservative management.

Those children with an uncertain diagnosis require either further diagnostic studies or observation, depending on the likelihood of appendicitis and the duration of symptoms. Observation may be done at home or in the hospital. If the diagnosis ultimately is appendicitis, the incidence of perforation is significantly higher (60% vs. 30%) if observation is carried out at home.

Once the diagnosis of appendicitis is made or highly suspect, the treatment is surgical appendectomy. Meckel diverticulitis may mimic appendicitis and is usually diagnosed at surgery (see Chapter 312.2).

Treatment.

Children with nonperforated appendicitis require minimal preoperative preparation with intravenous fluids and antibiotics. Although the use of antibiotics in uncomplicated appendicitis is controversial, it has decreased the incidence of postoperative wound infections. Pain should be managed effectively with intravenous morphine even before the diagnosis is confirmed because such therapy does not adversely affect the examination or delay the diagnosis. Appendectomy should be done within a few hours of establishing the diagnosis and is usually performed through a right lower quadrant incision. Laparoscopic appendectomy has been used in children, although some studies have reported complication rates (intra-abdominal abscess formation) higher than those for open appendectomy. Further evaluation is needed before a definitive comparison of open and laparoscopic appendectomy can be made. In children with an uncertain diagnosis, particularly adolescent females, the laparoscopic approach has the advantage of allowing wider intraperitoneal exploration. Laparoscopy is associated with a shorter recovery period and a lower incidence of wound infection without a longer operative time. Appendectomy for nonperforated appendicitis is associated with a low complication rate, rapid recovery, and short (2–3 days) hospitalization.

If the appendix has perforated, especially with generalized peritonitis, significant fluid resuscitation and broad-spectrum antibiotics may be required a few hours before appendectomy. Nasogastric suction should be used if the patient has significant vomiting or abdominal distention. Antibiotics should cover the commonly encountered organisms (*Bacteroides, Escherichia coli, Klebsiella,* and *Pseudomonas* species). The commonly used intravenous regimens include ampicillin (100?mg/kg/24?hr), gentamicin (5?mg/kg/24?hr), and clindamycin (25–40?mg/kg/24?hr) or metronidazole (Flagyl) (30?mg/kg/24?hr). Appendectomy is performed with or without drainage of the peritoneal cavity, and antibiotics are continued for 7–10 days. Occasionally, a localized abscess is treated with antibiotics with or without open or percutaneous drainage with appendectomy scheduled as a second elective procedure in 4–6 wk. If antibiotics are successful, some clinicians question the need for a planned appendectomy. In perforated appendicitis, the postoperative course is characterized by continued fluid requirement, fever, intra-abdominal abscess formation, sepsis, and prolonged (4–5 days) paralytic ileus.

Complications.

Complications occur in 25–30% of children with appendicitis, primarily those with perforation. The most effective method of reducing complications of appendicitis is to reduce the incidence of perforation. Mortality from appendicitis is low (0.5–1%). The complications are primarily infectious. Wound infection complicates recovery in 0–2% of children with nonperforated appendicitis and in 10–15% of those with perforated appendicitis. Treatment consists of opening the wound with healing by secondary intention. Further antibiotics are not necessary unless the patient has associated cellulitis or systemic signs of toxicity. Intra-abdominal abscess is rare in simple appendicitis but occurs in 4–6% of children with perforation. Usually, the abscess in the right lower quadrant is solitary and, if needed, can be drained by a CT-guided or ultrasonogram-guided percutaneous approach. Multiple intra-abdominal abscesses are best treated by open laparotomy with drainage. Liver abscess from portal vein sepsis is uncommon but may require multiple drainage procedures.

Intestinal obstruction is a common complication and is usually managed with nasogastric suction if it occurs in the early postoperative period. Infertility caused by adhesions or obstruction of the distal fallopian tube is not associated with simple appendicitis but is three to four times more likely after perforation.

Chapter 325 - Surgical Conditions of the Anus, Rectum, and Colon

Alberto Peña

In infants and children, close inspection of the anal area is as valuable as a digital rectal examination. *Fissures* can be best identified by having a parent hold the infant's hips in acute flexion so that the examiner can separate the patient's buttocks, using both thumbs, gently stretching the anus and everting the lining to expose the fissure. In all cases of constipation, especially when an obstruction is possible, a digital examination is indicated, after assessing perianal sensation. Properly done, this examination should cause little or no discomfort to the patient. A well-lubricated finger is passed over the anus a few times to accustom the patient to the unusual sensation. Then the pulp of the index or fifth finger is pressed against the anus with increasing flexion of the interphalangeal joints and the finger slips easily into the anal canal.

325.1 Anorectal Malformations

Anorectal malformations include a spectrum of defects. Some are complex, difficult to manage, and associated with important anatomic deficiencies and therefore have a poor functional prognosis. Others are minor and easily treated, having an excellent functional prognosis. The main concerns are future bowel control and urinary and sexual function. Anorectal anomalies occur in about 1/4,000 live births and manifest various grades from anal stenosis to agenesis or from rectal agenesis to atresia.

Embryology and Pathogenesis.

The origin of the anus and the rectum is an embryologic structure called the cloaca. Lateral ingrowths of this structure form the urorectal septum, separating the rectum dorsally from the urinary tract ventrally. Both

systems (rectum and urinary tract) become completely separated by the 7th wk of gestation. At this same time, the urogenital portion of the original cloaca already has an external opening, whereas the anal portion is closed by a membrane that opens by the 8th wk of gestation.

Abnormalities in the development of these processes at varying stages provoke a spectrum of anomalies, most of which affect the lower intestinal tract and the genitourinary structures. Persistence of communication between the genitourinary and rectal portions of the cloaca results in fistulas.

Pathology and Classification

MALE PATIENTS

Perineal Fistula. Perineal (cutaneous) fistula is the simplest defect in both sexes. Patients have a small orifice located in the perineum, anterior to the center of the external sphincter, close to the scrotum in the male or to the vulva in the female. Male patients frequently have in their perineum a “bucket handle”-type malformation or a “black ribbon”-type structure that represents a subepithelial fistula filled with meconium. These patients usually have a well-formed sacrum, a prominent midline groove, and a prominent anal dimple. The frequency of associated defects affecting other organs is less than 10%. The diagnosis is established by simple perineal inspection. Unfortunately, the diagnosis of this particular defect is frequently missed, owing to an inadequate neonatal examination. A missed or delayed diagnosis may have significant clinical implications, mainly involving exacerbation of constipation. No further investigations are required, and this defect can be repaired without a protective colostomy.

Rectourethral Fistula. In cases of rectourethral fistula, the rectum communicates with the lower part of the urethra (bulbar urethra) or the upper part of the urethra (prostatic urethra). The sphincteric mechanism usually is satisfactory; a few patients have poor perineal muscles and a flat-looking perineum. The sacrum may have different degrees of hypodevelopment, particularly in cases of rectourethral prostatic fistula. Most of these patients have a well-formed midline perineal groove and an anal dimple. Those with a rectoprostatic fistula have a poorly developed sacrum, frequently a flat perineum, a bifid scrotum, and an anal dimple located very close to the scrotum. These patients require a protective colostomy during the newborn period. The complete surgical repair is performed later in life. Rectourethral fistula represents the most frequent anorectal defect seen in male patients.

Rectovesical Fistula. In patients having rectovesical fistulas, the rectum communicates with the urinary tract at the level of the bladder neck. The rectal sphincteric mechanism is usually poorly developed. The sacrum is frequently deformed and is often absent. The perineum looks flat. This defect represents 10% of the total number of affected male patients. The prognosis for bowel function is usually poor. A colostomy is mandatory during the newborn period, followed by corrective surgical repair later in life.

Imperforate Anus Without Fistula. This defect has the same characteristics in both sexes. The rectum is completely blind and is usually found approximately 2?cm above the perineal skin. The sacrum and the sphincteric mechanism are usually well developed. The functional prognosis is usually good and is similar to that in those male patients with a rectourethral bulbar fistula. A colostomy is indicated during the

newborn period. This defect is frequently associated with Down syndrome. When properly operated on, patients who have this defect and Down syndrome have the same good prognosis for bowel function as chromosomally normal children.

Rectal Atresia. Rectal atresia is a rare defect occurring in only 1% of anorectal anomalies. It has the same characteristics in both sexes. The unique feature of this defect is that affected patients have a normal anal canal and a normal anus. The defect is frequently discovered while a rectal temperature is being taken. An obstruction is present about 2?cm above the skin level. These patients need a protective colostomy. The functional prognosis is excellent because they have a normal sphincteric mechanism (and normal sensation), which resides in the anal canal.

FEMALE PATIENTS

Vestibular Fistula. Vestibular fistula is the most frequent defect seen in females. The rectum opens in the vestibule of the female genitalia immediately outside the hymen orifice. Patients are frequently mislabeled as having “rectovaginal fistula.” The functional prognosis is excellent. The sacrum is usually normal, and the perineum shows a prominent midline groove and a noticeable anal dimple, all of which indicate that the sphincteric mechanism is intact. A protective colostomy is needed before the corrective surgical procedure, although this colostomy does not need to be performed on an emergency basis because the fistula is frequently competent to decompress the intestinal tract.

Persistent Cloaca. In cases of persistent cloaca, the rectum, vagina, and urinary tract meet and fuse into a single common channel. The perineum shows a single orifice located immediately behind the clitoris. The length of the common channels varies from 1–10?cm; this has important technical and prognostic implications. Patients with short common channels (<3?cm) usually have well-developed sacrums and good sphincters. A common channel longer than 3?cm usually suggests that the patient has a more complex defect and, frequently, has a poor sphincteric mechanism and a poor sacrum. Most patients with cloacas have an abnormally large vagina filled with mucous secretions (hydrocolpos). Different degrees of vaginal and uterine septation also are present. A diverting colostomy is indicated at birth; in addition, patients with a cloaca represent a urologic emergency because approximately 90% have associated urologic defects. Before the colostomy, the urologic diagnosis must be established to decompress the urinary tract, if necessary, at the same time the colostomy is created.

The term *rectovaginal fistula* is not used in this classification because true rectovaginal fistulas are extremely unusual defects.

Diagnosis and Early Management.

Two important questions must be answered during the first 24 hours of life for neonates with anorectal malformations:

1. Does the neonate suffer from a serious associated defect that endangers life and requires urgent treatment?
2. Can the neonate be treated with an anoplasty or pull-through without a colostomy or is a colostomy needed?

The associated defects represent the main risk for the patient's life. The infant needs kidney, spinal, and pelvic ultrasonograms, an echocardiogram, a radiograph of the sacrum and lumbar spine, and close clinical observation for signs and symptoms of esophageal atresia and/or intestinal obstruction. The second question is answered after 24?hr because before that period imaging studies are not accurate.

MALE PATIENTS.

Good clinical evaluation and a urinalysis provide sufficient information in 80–90% of patients to decide whether a colostomy is needed. If a patient has a perineal or rectourinary fistula, meconium may not be seen at the perineum or in the urine before 16–24?hr after birth. The most distal part of the bowel, in cases of perineal and rectourethral fistulas, is surrounded by voluntary sphincteric muscles; the intraluminal bowel pressure must be high enough to overcome the tone of those muscles before one can see meconium in the urine or in the perineum. At birth, the bowel is not distended; therefore, clinical and radiologic evaluations are not reliable during the first 16–24?hr of life. A piece of gauze is placed around the tip of the penis, and the nurse is instructed to check for particles of meconium filtered through this gauze. The presence of meconium in the urine and a flat bottom are considered indications to

create a protective colostomy. Clinical findings consistent with the diagnosis of a perineal fistula represent an indication for an anoplasty without a protective colostomy. Sometimes none of the clinical signs already described becomes evident after 24?hr of observation; a radiologic evaluation is then indicated. A cross-table lateral film with the patient in a prone position taken after 16–24?hr of life is valuable for determining the position of the rectal pouch. When this pouch is separated from the skin by more than 1?cm, the patient needs a colostomy. During the first 24?hr of life, all these patients need renal and bladder ultrasound evaluation to identify an obstructive uropathy.

FEMALE PATIENTS.

More than 90% of the time, the diagnosis can be established by a meticulous perineal inspection. These patients must be observed during the first 16–24?hr of life. The presence of a single perineal orifice is pathognomonic of a cloaca. A palpable pelvic mass (hydrocolpos) reinforces the suspicion of a cloaca. The diagnosis of a vestibular fistula can be established by careful separation of the labia to see the vestibule. The rectal orifice is located immediately behind the hymen within the female genitalia and in the vestibule. A perineal fistula is easy to diagnose. The rectal orifice is located somewhere between the female genitalia and the center of the sphincter and is surrounded by skin; the term *anterior anus,* which is sometimes used for this defect, is inadequate because these are abnormal fistula orifices not surrounded by a normal sphincteric mechanism. Fewer than 10% of these patients fail to pass meconium through the genitalia or perineum after 24?hr of observation. Those patients may require a cross-table lateral film. They also need a

renal and bladder ultrasound study of the abdomen during the first 24?hr of life, because patients with persistent cloaca have the highest incidence of urologic defects.

Associated Defects.

About 50% of children with anorectal anomalies have a urologic problem. The more serious and complex the anorectal defect, the more frequently it is associated with a urologic anomaly. Male patients with a rectovesical fistula and patients with a persistent cloaca have a 90% chance of having a urologic defect. On the other hand, patients with a rectoperineal fistula have less than a 10% chance. Urologic evaluation must be established before performing a colostomy. Untreated acidosis and sepsis resulting from an undetected obstructive uropathy are risks.

A good correlation exists between the degree of sacral development and the final functional prognosis. Patients with an absent sacrum have permanent fecal and urinary incontinence. Different degrees of sacral malformations are associated with important functional sequelae. Spinal abnormalities and different degrees of dysraphism are frequently associated with these defects. Tethered cord occurs in approximately 25% of patients with anorectal malformations; severe anorectal defects have a poor prognosis. It is important to establish the diagnosis to aid neurosurgical treatment. The diagnosis of spinal defects can be established during the first 3 mo of life by spinal ultrasound; in older patients, it is necessary to use magnetic resonance imaging. Other associated congenital malformations include esophageal atresia, duodenal atresia, and cardiovascular defects.

Treatment.

Perineal fistulas are treated by a simple anoplasty without a protective colostomy; the operation is performed during the newborn period. The fistula orifice is moved back to the center of the external sphincter. Anal dilations are started 2 wk after the operation and are gradually increased to reach the size of a normal anus. All other defects are best managed during the newborn period with a protective colostomy. Later in life (1–12 mo), corrective surgical repair is performed. Lately, the tendency is toward the repair of most malformations during the newborn period without a protective colostomy. This approach could save these patients two operations (colostomy opening and colostomy closure). Serious complications and sequelae may occur after these operations; therefore, experienced surgeons, under controlled circumstances, should perform the neonatal approach without a colostomy. The patients must be carefully followed, and the results as well as the complications must be reported.

A posterior sagittal approach uses an electric muscle stimulator to identify the sphincteric mechanism. This approach allows a direct exposure to the internal anatomy, thus avoiding potential damage to important structures and nerves. A midline incision between both buttocks is used to split all the muscle structures in the midline. The rectum is separated from the genitourinary tract and, in cases of cloaca, the vagina and the urinary tract. The rectum is placed within the limits of the electrically determined sphincteric mechanism. The vagina and urinary tract are also reconstructed in cases of cloaca. Sometimes the rectum is too ectatic to be accommodated within the available space; therefore, the rectum has to be tailored accordingly. In male patients, the malformation can be repaired posterosagittally 90% of the time. The remaining 10% of patients have a rectovesical fistula because the rectum cannot be reached posterosagittally; a combined posterior sagittal and abdominal approach is needed. In cases of persistent cloaca, the abdomen must be opened in addition to the posterior sagittal approach, in 30–40% of patients, to mobilize a high rectum or high vagina. Laparoscopy has also been used to repair anorectal malformations. This novel form of treatment can conceivably avoid a laparotomy in those patients who would normally require such an approach. Larger series of patients and long-term follow-up of them are expected to determine the value of this therapeutic modality.

Two weeks after corrective surgery, the patients must be subjected to a protocol of anal dilations. These are done twice per day; every week a larger size dilator is passed to stretch the anus to normal size.

Prognosis.

Patients of both sexes with perineal fistula and rectal atresia should have excellent functional results after the repair of their defects; they should be fully continent. Male patients with rectourethral bulbar fistula and patients of both sexes with imperforate anus without a fistula also have good prognosis. About 80% achieve bowel control between 3 and 4 yr of age. A significant number may occasionally suffer from minimal soiling.

Male patients with rectourethral prostatic fistula have about a 60% chance of having bowel control by the age of 3 yr. Male patients with rectovesical fistula have a poor functional prognosis. Only about 20% have voluntary bowel movements by the age of 3 yr.

An extremely abnormal sacrum usually means that the patient will have *fecal incontinence.* An extremely abnormal sacrum is most often associated with rectovesical fistula or rectoprostatic fistula. One rarely finds a good prognostic type of defect, such as perineal or vestibular fistula, associated with a poor sacrum. More than 90% of female patients with rectovestibular fistula have voluntary bowel movements by the age of 3 yr; few have occasional soiling.

Patients with a persistent cloaca with a common channel of less than 3?cm have about an 80% chance of having voluntary bowel movements by the age of 3 yr; most are urine continent. When the common channel is longer than 3?cm, most are fecal incontinent and require intermittent catheterization to empty their bladder. Patients with a persistent cloaca with a common channel longer than 3?cm usually have an extremely abnormal sacrum.

Approximately 25% of all patients have fecal incontinence, and about 70% of those with a cloaca with a long common channel need intermittent catheterization to empty the bladder. When these patients are old enough to be socially active, a medical program for bowel management and urinary control must be implemented. The use of enemas, suppositories, colonic

irrigations, specific diets, and sometimes medications to regulate the motility of the colon will allow them to keep clean for 24?hr, thus improving their quality of life. Patients with fecal incontinence who have intractable diarrhea are usually refractory to medical management and require a permanent colostomy.

Most patients subjected to an operation to repair an imperforate anus have varying degrees of constipation. This symptom is more severe in patients with lower and simpler defects. Patients who had inadequate colostomies (loop colostomies that allow the passing of stool from the proximal into the distal limb of the bowel) may subsequently have constipation. These patients need a diet rich in fiber and, sometimes, laxatives to empty the rectum daily. Ineffective medical treatment may exacerbate the problem; the rectosigmoid colon continues to enlarge and becomes inefficient in emptying, making treatment a more difficult task.

325.2 Anal Fissure

Anal fissure is a small laceration of the mucocutaneous junction of the anus. It is an acquired lesion secondary to the forceful passage of a hard stool, mainly seen in infancy. Fissures may be the consequence and not the cause of constipation.

Clinical Manifestations.

Usually, a history of constipation is elicited. At some point, the patient had a painful bowel movement, which may correspond to the actual event of fissure formation after the passing of hard stool. Then, in addition to the primary cause of constipation, the patient retains stool voluntarily to avoid a painful bowel movement. This exacerbates the constipation, and, eventually, the passing of harder and larger stools creates a vicious cycle. Pain on defecation and bright red blood on the surface of the stool may be observed. The diagnosis is established by inspection of the anal area. For this examination, the infant's hips are held in acute flexion, the buttocks are separated to expand the folds of the perianal skin, and the fissure becomes evident as a minor laceration. Sometimes, peripheral to the laceration, the patient has a little skin appendage that actually represents epithelialized granulomatous tissue, secondary to the chronic inflammation; this is usually known as a “tag.”

Treatment.

The most important element in the treatment of this condition is for the parents to understand the origin of the laceration and the mechanism of the cycle of constipation. The goal of the treatment is to reverse this cycle, which can be achieved only by guaranteeing that the patient has soft stools to avoid overstretching the anus. The healing process may take several days or even several weeks. One single episode of impaction with passing of a hard piece of stool may exacerbate the problem. A stool softener is indicated, but the parents must adjust the dose to the response of the patient. The goal is to avoid both hard stools and diarrhea. Simultaneously, the primary cause of the constipation must be treated when present. No scientific basis supports other types of treatments, including stretching of the anus, “internal” anal sphincterotomy, or excision of the fissure. Chronic anal fissures in older patients have been managed with the local injection of botulinum toxin to treat the associated contraction of the sphincter. The role of this agent in young children is not defined.

325.3 Perianal Abscess and Fistula

Perianal abscess and fistula can be seen in two different groups of pediatric patients with different cause, pathogenesis, and treatment. These include (1) infants with no predisposing conditions and (2) older children with predisposing conditions. This disorder is relatively common in the first group, which includes infants, usually boys younger than 2 yr. This is usually a benign, self-limited condition; the abscess has a communication with one of the crypts of the pectinate line of the anal canal. It is believed that the crypt is the source of contamination; the exact mechanism is unknown. The abscess eventually drains through an orifice in the perianal area. After this drainage, the inflammation subsides, but a fistula remains that communicates with the affected crypt to the perianal external orifice. This condition can be

demonstrated during surgical treatment. The fistula becomes chronic but usually disappears spontaneously before 2 yr of age. This fistula is located close to the lumen of the anus, a feature that makes this a very benign condition because the sphincteric mechanism is not affected.

The second group includes patients older than 2 yr with perianal or perirectal abscess and with a predisposing illness, including drug-induced or autoimmune neutropenia, leukemia, AIDS, diabetes mellitus, Crohn disease, prior rectal surgery (Hirschsprung disease, imperforate anus), or sequelae from the use of immunosuppressant drugs. This is considered a much more serious condition; the prognosis is intimately related to that of the predisposing disease. The abscess may be deep and may rapidly expand with severe toxic symptoms, particularly when the predisposing illness is associated with immunosuppression or neutropenia. Bacteriologic examination of abscess material reveals mixed aerobic *(Escherichia coli, Klebsiella pneumoniae, Staphylococcus aureus)* and anaerobic *(Bacteroides* species, *Clostridium, Veillonella)* flora. Ten to 15% yield pure growth of *E. coli, S. aureus,* or *Bacteroides fragilis.* Neutropenic patients may also have bacteremia that inconsistently has the same organism as the abscess.

Clinical Manifestations.

The infants with no predisposing conditions have mild clinical manifestations, sometimes including low-grade fever, mild rectal pain, and an area of perianal cellulitis. Subsequently, a pustule is formed and the abscess drains through that orifice. This alleviates the symptoms. The inflammation disappears and the pustule heals. However, one or several weeks later, the draining of pus reappears and continues in an intermittent, chronic way. Left alone, this condition usually heals spontaneously before 2 yr of age.

Children with predisposing conditions have a much more serious clinical course. They may or may not have fever depending on their immunologic status. Cellulitis may rapidly expand with warmth, erythema, induration, tenderness, and fluctuation over the ischiorectal fossa, requiring aggressive treatment. Patients may experience severe toxicity and may become septic. In addition, they may show symptoms of the predisposing illness.

Treatment.

Infants with no predisposing disease usually do not require any treatment because this condition is self-limited. No

evidence indicates that antibiotics are useful in these patients. Occasionally, when the patient is extremely uncomfortable, the abscess can be drained under local anesthesia. This alleviates the symptoms of pain and fever but does not eliminate the possibility of a fistula formation. Once a chronic fistula has formed, most clinicians recommend a *fistulotomy* under general anesthesia. The anal canal and lower part of the rectum are exposed with an adequate retractor, and a lacrimal probe is passed through the external orifice of the fistula, coming out through one of the crypts. The tissue between the fistula and the lumen of the anal canal is divided with cautery. The wound is left open to granulate spontaneously. This treatment usually runs a 20% chance of recurrence. Conservative management (observation) is also accepted because in most cases the fistula disappears spontaneously before 2 yr of age.

Older children with predisposing diseases may require more aggressive treatment and treatment of the predisposing condition. Antibiotics must be administered, including a combination that covers enteric gram-negative organisms, *S. aureus,* and fecal anaerobic flora. Wide excision and drainage are mandatory in cases of sepsis and expanding cellulitis.

Fistulas in older patients are mainly associated with Crohn disease or with a history of pull-through surgery for the treatment of Hirschsprung disease. Those fistulas are difficult to treat. The treatment is the same as that of the predisposing condition.

325.4 Hemorrhoids

Hemorrhoids in children are uncommon and are usually benign. When a hemorrhoid is seen, one must suspect portal hypertension. Infants are sometimes brought for consultation after an incidental finding of a hemorrhoid. These follow a benign course. No reports of thrombosis or other complications of hemorrhoids exist in children; therefore, they should be managed conservatively. Chronic constipation, fecal impaction, or any other kind of irritating local factors must be treated to avoid exacerbation of this condition.

325.5 Rectal Prolapse

Rectal prolapse refers to the exteriorization of the rectal mucosa through the anus. When this extrusion includes all the layers of the rectal wall, it is called *procidentia.* Most cases of rectal tissue protruding through the anus are prolapse and not polyps, intussusception, or other tissue.

Most cases of prolapse are idiopathic. The onset is often between age 1 and 5 yr (mean, age 3 yr). Predisposing factors include intestinal parasites (particularly in endemic areas), malnutrition, diarrhea, ulcerative colitis, pertussis, Ehlers-Danlos syndrome, meningocele (more frequently associated with procidentia owing to the lack of perineal muscle support), cystic fibrosis, and chronic constipation. Patients treated surgically for imperforate anus may have different degrees of rectomucosal prolapse. This is particularly common in patients with poor sphincteric development.

Clinical Manifestations.

Prolapse of the rectum usually occurs during defecation. Afterward, the prolapse is reduced sometimes spontaneously or manually by the patient or parent. In very severe cases, the prolapsed rectum remains chronically exteriorized, becoming congested and edematous, which makes it more difficult to reduce. Rectal prolapse is usually painless or is associated with a mild discomfort. When the rectum remains prolapsed after defecation, it may be traumatized by underwear and may produce

bleeding and wetness. Eventually, the exposed rectum becomes ulcerated. The protruding mass varies from bright red to dark red; it may be as long as 10–12?cm. See Chapter 326 for a distinction from a prolapsed polyp.

Treatment.

The evaluation should include all the necessary tests to rule out the already stated predisposing conditions. *Reduction of protrusion* is aided by pressure with warm compresses. An easy method of reduction is to cover the finger with a piece of toilet paper, introduce it into the lumen of the mass, and gently push it into the patient's rectum. The finger is then immediately withdrawn. The toilet paper adheres to the mucous membrane, permitting release of the finger; the paper, when softened, is later expelled.

General measures should include careful manual reduction of the prolapse after an episode of defecation, attempts to avoid excessive pushing during bowel movements (with patient's feet off the floor), use of laxatives and stool softeners in cases of constipation, avoidance of inflammatory conditions of the rectum, and treatment of intestinal parasitosis when present. If all this fails, surgical treatment may be indicated. None of the existing operations is considered ideal because each has risks and disadvantages. Therefore, medical treatment should always be tried first. Operations include the placement of a subcutaneous, ringlike band in the perianal area to decrease the diameter of the anus. Significant numbers of patients become asymptomatic with this treatment; some may experience megacolon, owing to a mechanical anal obstruction. Injection of sclerosing substances in the perirectal area has been reported but has the risk of nerve damage and infection. A posterior incision of the rectum, with anchoring of the rectum to the presacral periosteum, represents a useful alternative in severe cases. In cases of procidentia associated with myelomeningocele, patients may require laparotomy and internal fixation of the rectum to the presacral fascia.

325.6 Pilonidal Sinus and Abscess

A dimple located in the midline intergluteal cleft, at the level of the coccyx, is seen relatively frequently in normal infants. No evidence indicates that this little pilonidal sinus provokes any problems for the patient. Malignant degeneration of pilonidal sinus cyst has been reported only in patients with chronic infections and abscesses. An open dermal sinus is a benign condition and is usually asymptomatic.

Pilonidal abscesses occur in adolescent patients. Why this condition is not seen in younger patients is unknown. The abscess may require incision and drainage during the acute stage, and, subsequently, it requires en bloc resection to remove all the epithelial tract that caused the problem.

Joel Shilyansky

Familial Polyposis Syndromes.

The familial syndromes associated with intestinal polyps are particularly important because of the malignant potential of the lesions. Children need to be followed regularly, and a plan for appropriate intervention should be formulated in advance (Table 326–1).

TABLE 326-1 -- Gastrointestinal Polyps in Children

Syndrome	Gene Defect	Histology	Frequency	Gastrointestinal Cancer Risk
Common juvenile polyps	Unknown	Hamartoma	1:100 to 1:50	None*
FAP coli (including Gardner's and Turcot's variants)	*APC*	Adenoma	1:17,000 to 1:5,000	100%
PJS	*LKB1 (STK11)*; ? others	Hamartoma	1:120,000	Increased
CS	*PTEN*; ? others	Hamartoma	Rare	Uncertain
BRRS	*PTEN*; ? others	Hamartoma	Rare	None
Juvenile polyposis	*SMAD4*; ? *PTEN*; ? others	Hamartoma	Rare	50%

FAP = familial adematous polyposis; APC = adenomatous polyposis coli; PJS = Peutz-Jeghers syndrome; CS = Cowden syndrome; BRRS = Bannayan-Riley-Ruvalcaba syndrome; PTEN = protein tyrosine phosphatase and tensin homolog.

From Corredor J, et al: Gastrointestinal polyps in children: Advances in molecular genetics, diagnosis and management. J. Pediatr 2001;138:621–28.

**If solitary.*

Juvenile colonic polyps, also known as retention or inflammatory polyps, are the most common childhood bowel tumors, present in 1–3% of people younger than 21 yr old. Polyps rarely appear before 1 yr of age, and most present between 2–10 yr of age. Juvenile polyps are uncommon beyond age 15 yr. The polyps are evenly distributed through the colon. Solitary polyps are common; two or more may occur. Most juvenile polyps are erythematous, friable, and pedunculated and range in size from a few millimeters to 3?cm. Histologic examination demonstrates hamartomatous proliferation of mucus-filled glandular and stromal elements, marked vascularity, and infiltration with lymphocytes, eosinophils, and polymorphonuclear and plasma cells. The polyps have characteristic mucus-filled cystic glands and are covered by a fragile, single layer of epithelium. The typical juvenile polyp with no adenomatous change has no potential for malignancy. Juvenile polyps with an adenomatous component have rarely been reported (see Table 326–1).

Clinical manifestations usually include bright red, painless, rectal bleeding during or immediately after defecation. Exsanguinating hemorrhage is rare; bleeding often stops spontaneously. Iron-deficiency anemia is present in 30% of children, but it is rarely the initial chief complaint. Lower abdominal pain and cramps are uncommon and are associated with intussusception. Prolapsed polyps appear as dark, beefy red, pedunculated masses, in distinction to the lighter pink mucosal appearance of rectal prolapse. Perianal pruritus and mucous discharge are often associated with prolapse. Spontaneous polyp infarction and self-amputation are common; diarrhea and obstruction are uncommon. The differential diagnosis includes other forms of intestinal polyposis, Meckel diverticulum, anal fissure, inflammatory bowel disease, intestinal infections, Henoch-Schönlein purpura, and coagulation disorders.

The *diagnosis* is usually made by colonoscopy. Polyps appear as smooth, pedunculated lesions. Air-contrast barium enema can demonstrate polyps, but colonoscopy would still be required for treatment. *Treatment* includes the removal of the polyp at colonoscopy by snare cautery or, rarely, by transabdominal polypectomy. Retrieval of polyps for histologic confirmation of the diagnosis should always be performed. Recurrences occasionally are seen.

Multiple juvenile colonic polyps (more than three to five) occur in families as an autosomal dominant trait and are associated with congenital anomalies (20% of new cases are sporadic). In a subset of families, inactivating mutations are found in the *SMAD4* and bone morphogenetic protein receptor 1A genes, resulting in interruption of intracellular signaling of the transforming growth factor-ß. These polyps are identical to solitary polyps; however, afflicted individuals are at greatly increased risk for gastrointestinal cancer (~50%). Children can present with painless bleeding or, rarely, when the entire gastrointestinal tract is involved, with failure to thrive,

malabsorption, anemia, hypoalbuminemia, and abdominal pain.

The risk of cancer is low in patients without a family history of cancer and two or fewer polyps, whereas patients with three or more polyps are at increased risk for malignancy. Patients with multiple juvenile polyps or a family history of juvenile polyposis should undergo colonoscopy every 3 yr. The frequency of examinations should increase in adult patients (see Table 326–1).

Cowden syndrome (CS) and **Bannayan-Riley-Ruvalcaba syndrome (BRRS)** are rare autosomal dominant syndromes associated with multiple, distinct anomalies and hamartomas in skin (99% of patients), breast, thyroid, endometrium, brain, and the gastrointestinal tract (60% of patients). Both syndromes are associated with mutations in a tumor suppressor gene termed *protein tyrosine phosphatase and tensin homologue (PTEN)*. Affected individuals are at increased risk for cancer of the thyroid and breast, whereas the risk of gastrointestinal neoplasms is uncertain (see Table 326–1).

Familial Adenomatous Polyposis Coli (FAP).

Large numbers of adenomatous lesions throughout the colon characterizes these autosomal dominant, premalignant conditions. All are caused by germ line mutations in the adenomatous polyposis coli *(APC)* gene, a tumor suppressor gene localized to chromosome 5q21. *APC* gene mutations result in truncation of the cytoplasmic protein, which is responsible for binding and regulating the degradation of ß-catenin. Intracellular accumulation of ß-catenin may have a role in the formation of adenomas. The incidence of FAP is 1 in 5,000 to 17,000 persons, with usual onset of polyp development late in the 1st decade of life or during adolescence. By definition, more than five adenomatous polyps are present in the colon at the time of diagnosis. Usually more than 100 (often 1,000) visible adenomas are present when the patient is in the 2nd or 3rd decade. Congenital hypertrophy of retinal pigment epithelial cells is also present from birth in most patients. Variability in the clinical features, including extracolonic manifestations, depends on the location of the mutation on the *APC* gene. Thus, mutations of the *APC* gene are also responsible for **Gardner syndrome** (multiple colorectal polyps, periampullary polyps, osteomas [mandibular], lipomas, fibromas, epidermoid cysts, and desmoid tumors) and some but not all cases of **Turcot syndrome** (primary brain tumor/medulloblastoma and multiple colorectal polyposis). The soft tissue lesions (desmoid tumors) and osteomas may appear during childhood, whereas intestinal polyps may not become apparent until adolescence or early adult life. These premalignant polyps may develop anywhere along the digestive tract, but colonic and duodenal (periampullary) lesions predominate. The relative risk of hepatoblastoma, thyroid carcinoma, and cholangiocarcinoma is also increased. Some families who do not meet the criteria for familial adenomatous polyposis coli but who have a high frequency of adenomatous polyps and colonic cancer may also have a mutation of the *APC* gene (see Table 326–1).

Clinically, initially, the polyps are asymptomatic; many often remain so. When symptomatic, adenomatous polyps cause

hematochezia, occasionally cramps, or, rarely, diarrhea. Malignancy arising from pre-existing adenomatous polyps has been reported in children as young as 10 yr of age, although these lesions more commonly appear in young adults. Most affected individuals will have cancer by age 40 yr.

The *diagnosis* should be suspected from the family history and confirmed by colonoscopy. The polyps are numerous; biopsies demonstrate the adenomatous nature in contrast to the inflammatory and cystic finding of juvenile polyps. *APC* gene mutations are detected in 80–90% of families with FAP, a finding allowing for presymptomatic testing in association with genetic counseling. If a mutation is identified in the index patient, affected family members can be differentiated from unaffected members by gene testing. If the index patient is among the 10–20% of individuals with this disorder in whom the mutation is not defined, genetic testing of family members may identify novel mutations in the *APC* gene. Because a negative result can be misleading, caution should be exercised in counseling families. A child with diagnosed FAP or family history of FAP and a positive gene test should be followed with colonoscopy every 6–12 mo until definitive surgical treatment is undertaken. If genetic testing is negative in a family with an identified mutation, the child is likely not to have FAP. Patients with Gardner syndrome should also undergo regular gastroduodenoscopy and removal of gastric and duodenal polyps. Premalignant lesions of the ampulla of Vater occur in adulthood and can be usually treated with local resection.

Definitive *treatment* of FAP requires prophylactic proctocolectomy to prevent cancer. Ileoanal pull-through restores bowel continuity with excellent functional results. Although controversy regarding the timing of surgery exists, the success of reconstruction has allowed earlier resection, thus averting the risk of invasive carcinoma. Nonsteroidal anti-inflammatory drugs, such as sulindac, and more selective cyclooxygenase-2 inhibitors, such as celecoxib, may slow polyp development; however, their efficacy in preventing malignant transformation is currently unknown and their use remains investigational.

Peutz-Jeghers Syndrome (PJS).

This rare, autosomal dominant inherited syndrome is characterized by mucosal pigmentation of the lips and gums and hamartomas of the gastrointestinal tract. Deeply pigmented discrete freckles are seen at birth or appear during infancy on the lips and buccal mucosa and even around the mouth. Evidence of intestinal lesions may come from bleeding but more commonly may arise from crampy pain associated with obstruction due to recurrent intussusception.

Polyps in PJS are benign hamartomas characterized by a “frondlike” core of stromal tissue and smooth muscle surrounded by normal-appearing intestinal epithelium. Intestinal lesions should be excised if they are causing significant and persistent symptoms; involvement is usually too extensive to remove all the polyps.

Family studies and genetic counseling may reveal relatives with either partial or complete manifestations of the syndrome. Fifty per cent of patients, however, have

no family member with the disorder, a finding suggesting a high rate of new mutations. Inactivating mutations in a gene located on chromosome 19p13.3, *LKB1* (*STK11*) encoding a serine/threonine kinase has been implicated in the pathogenesis of PJS. Cancer develops in up to 50% of people having PJS, most commonly middle-aged adults. Colorectal, breast, and gynecologic tumors are seen most frequently. Mammography, gynecologic examination, and colonoscopy starting in the late 20s or early 30s are recommended (see Table 326–1).

Hemangioma.

These rare benign lesions can cause massive, even fatal, hemorrhage. The usual clinical manifestation is painless bleeding beginning in childhood. The blood loss can be subtle and chronic or sudden and massive. Usually, the patient has no additional intestinal symptoms, but intussusception with obstructive symptoms may occur. About 50% of patients have cutaneous hemangiomas; some have a family history of similar lesions. About half of these lesions are in the colon, where they may be seen by colonoscopy. Lesions that are more difficult to locate may be seen with the capsule-size ingested camera. During a period of bleeding, selective mesenteric arteriography may be useful in locating a lesion.

Leiomyoma.

This rare benign tumor occurs most commonly in the stomach, jejunum, and distal ileum. It can remain asymptomatic for long periods. Symptoms may result from intussusception, volvulus, central necrosis, and obstruction. Leiomyoma may be difficult to differentiate from leiomyosarcoma, a malignant tumor that occurs rarely in the gastrointestinal tract in children. Smooth muscle tumors occur at increased frequency in children with AIDS or immunosuppression after transplantation.

Carcinoma.

Epithelial tumors of the digestive tract are rare in children. Several childhood conditions predispose to development of gastrointestinal adenocarcinoma in early adulthood, for example, FAP, hereditary nonpolyposis colon carcinoma (HNPCC), Peutz-Jeghers syndrome, juvenile polyposis coli, ulcerative colitis, and, to a lesser extent, Crohn disease and disorders associated with chromosomal fragility. The usual site is the colon, but gastric and duodenal lesions are reported. Diagnosis is made based on family history, endoscopic findings, gastrointestinal bleeding, or obstruction. Symptoms are nonspecific abdominal pain, an abdominal mass, and, less frequently, hemorrhage. The tumors are relatively undifferentiated and highly malignant. The treatment of colorectal carcinoma is primarily surgical. Prognosis is related to stage of disease. Carcinoma of the colon without any known predisposing factors is an extremely rare occurrence in children. Thus it is important to obtain a complete family history and provide effective genetic screening and counseling to cancer patients (index cases) and their families to identify family members at risk. Mutations in the *APC* gene, leading to FAP and DNA mismatch repair genes *(hMSH2, hMSH6, PMS1, PMS2 and hMLH1),* leading to HNPCC are most commonly associated with colorectal carcinoma in children and young adults. Diagnosis of HNPCC should be suspected in the presence of family history of early-onset colon carcinoma and could be confirmed by genetic analysis. While the great majority of patients with HPNCC do not develop cancers until adulthood, the author has encountered two cases of colon carcinoma in teenagers. The age to begin endoscopic surveillance remains controversial and should be tailored to the individual patient. In addition, the risk of uterine, ovarian, pancreatic, biliary, and gastric cancer is also increased. Ethical, social, and psychological impact must be considered when genetic screening is contemplated. Carcinoma of the stomach is very rare, mimics the disease in adults, and may be associated with HNPCC and hereditary diffuse gastric cancer syndrome (HDGC). HDGC, an autosomal dominant inherited disorder, is caused by inactivating germline mutations in *CDH1*, a gene encoding E-cadherin, a calcium dependent adhesion protein that regulates the localization and function of the catenins. Genetic screening for *CDH1* mutations and prophylactic gastrectomy for carriers are controversial.

Lymphoma.

Lymphoma is the most common malignancy of the gastrointestinal tract in children (see Chapter 488). About 30% of children with non-Hodgkin lymphoma present with abdominal tumors. Disorders that predispose to lymphoma include AIDS, ataxia-telangiectasia, Wiskott-Aldrich syndrome, agammaglobulinemia, severe combined immunodeficiency syndrome, bone marrow or solid organ transplantation, and long-standing celiac disease. Lymphoma can arise in the stomach, distal ileum, cecum, or appendix and may present as crampy abdominal pain, vomiting,

TABLE 326-2 -- **Diarrhea Caused by Hormone-Secreting Tumors**

Name	Site	Hormone	Manifestations	Therapy
Carcinoid	Intestinal argentaffin cells Appendix, ileum, colon, jejunum, rectum Bronchial tree	Serotonin	Diarrhea, crampy abdominal pain, flushing, wheezing, cardiac valve damage	Somatostatin analogues; resection
Gastrinoma	Pancreas	Gastrin	Peptic ulcer, diarrhea	H_2 -blocking agents; omeprazole; tumor resection; gastrectomy

Mastocytoma	Cutaneous, intestine, liver, spleen	Histamine, VIP	Pruritus, flushing, apnea, if VIP(+) diarrhea	H_1 - and H_2 -blocking agents, cromolyn, steroids; resection if solitary
Medullary carcinoma	Thyroid	Calcitonin, VIP, prostaglandins	Watery diarrhea	Thyroidectomy
Ganglioneuroma, ganglioneuroblastoma, neuroblastoma, pheochromocytoma	Chromaffin cells; abdominal > other sites; extra-adrenal or adrenal	Catecholamines, VIP	Hypertension, tachycardia, sweating, anxiety, watery diarrhea*	ablockade for BP control; ßblockade for tachycardia; resection
Somatostatinoma	Pancreas	Somatostatin	Massive diarrhea	Resection
VIPoma	Pancreas	VIP	Watery diarrhea, achlorhydria, hypokalemia	Somatostatin analogues; resection

VIP = vasoactive intestinal polypeptide, BP = blood pressure, H_1 = histamine receptor type 1, H_2 = histamine receptor type 2.

**Diarrhea has been reported only in adult patients with pheochromocytoma.*

distention, or a palpable abdominal mass. Perforation is uncommon. Bowel lymphoma should be ruled out in children older than 3 yr of age presenting with an acute intussusception. It may be difficult to differentiate symptoms of small bowel lymphoma from Crohn disease.

Carcinoid Tumors.

These tumors of the enterochromaffin cells of the intestine usually occur in the appendix in children and are very low-grade malignancies. They may be found incidentally in the appendix at appendectomy. Complete resection with clear surgical margins of a carcinoid tumor of the appendix less than 1?cm in size is usually curative. Carcinoid tumors outside the appendix (ileojejunum, colon, and rectum in order of frequency) commonly metastasize; lesions metastatic to the liver can give rise to the carcinoid syndrome, which is the result of pharmacologically active hormones produced by the tumor. These produce episodic intestinal hypermotility and diarrhea, vasomotor disturbances (flushing), bronchoconstriction (wheezing), and right-sided heart failure. The most important active agent is serotonin; and finding high urinary levels of its metabolite, 5-hydroxyindoleacetic acid (5-HIAA), usually makes the diagnosis. The functional neoplasms are rare in children. Carcinoid may also spread to the small bowel mesentery, inducing severe retroperitoneal and mesenteric fibrosis. Treatment with long-acting somatostatin analogues can provide significant palliation.

Nodular Lymphoid Hyperplasia (NLH).

Lymphoid follicles in the lamina propria of the gut normally aggregate in Peyer patches, which are more prominent in the distal ileum. When hyperplastic they appear as submucosal nodules on contrast radiographs and may be mistaken for an abnormality. NLH may occur in the colon or the small bowel. Diffuse small bowel NLH may be seen in cases of immunoglobulin deficiency, with and without *Giardia lamblia* infestation. Patients may have rectal bleeding, diarrhea, and abdominal cramps, but symptoms are generally mild. In infants with dietary-protein hypersensitivity, NLH may occur in association with enterocolitis. NLH also has been noted to occur in inflammatory bowel disease and Castleman disease. The major importance of this entity is the similarity of its manifestations to more serious disorders. NLH usually resolves spontaneously and rarely requires specific treatment. Cyproheptadine or prednisone has been used for extreme bleeding or abdominal pain.

326.1 Diarrhea from Hormone-Secreting Tumors

Certain hormone-producing tumors cause a marked increase in intestinal secretion leading to severe chronic watery diarrhea (Table 326–2). The secretory diarrhea persists even if food is withheld. These tumors originate in the neural crest–derived APUD cells (*a*mine content, *p*recursor *u*ptake, amino acid *d*ecarboxylation) of the gastroenteropancreatic endocrine system and in adrenal or extra-adrenal neurogenic sites.

Diarrhea is massive and results in fluid and electrolyte imbalance and weight loss. Diagnosis is based on the presence of secretory watery diarrhea, extraintestinal manifestations, measurement of the suspected hormone or its metabolites in serum or urine, and various imaging techniques. If possible, tumor resection is the treatment of choice. Pharmacologic therapy with hormone antagonists such as long-acting synthetic somatostatin analogues may be palliative (see Table 326–2). Radioactively labeled somatostatin analogues have also been used as part of experimental treatment approaches.

Chapter 327 - Inguinal Hernias

John J. Aiken

Most inguinal hernias in infants and children are congenital indirect hernias caused by a patent processus vaginalis. Approximately 50% of inguinal hernias will present in the 1st year of life, most in the first 6 mo. Other types of inguinal hernias include direct (0.5–1%) and femoral (<0.5%). Risk factors for the development of an inguinal hernia include prematurity, developmental urogenital anomalies, conditions associated with abnormal abdominal fluid or increased intra-abdominal pressure, chronic respiratory disease, and inherited connective tissue disorders. Potential morbidity includes incarceration, strangulation, and gonadal or bowel infarction.

Embryology and Pathogenesis.

Most inguinal hernias in infants and children result from a persistent patency of the processus vaginalis. Based on their location in the inguinal canal (lateral to the inferior epigastric vessels) they are *indirect* hernias but are rarely associated with a muscular weakness or defect as would be typical of an adult hernia. The pertinent embryology of the inguinal region relates to the development and descent of the intra-abdominal testes and their relation to the processus vaginalis. Differentiation into testes or ovary occurs by 7 or 8 wk gestation. The processus vaginalis is present in the fetus at 12 wk gestation as a peritoneal outpouching that extends through the internal inguinal ring. The gubernaculum forms from the caudal end of the mesonephros and is attached to the lower pole of the testes. The processus vaginalis accompanies the testis as it exits the abdomen and descends into the scrotum under direction by the gubernaculum. The cordlike structures of the gubernaculum occasionally pass to ectopic locations (perineum or femoral region), resulting in ectopic testes. The testes descend from the urogenital ridge in the retroperitoneum to the area of the internal ring by about 28 wk gestation. Both androgenic hormones and mechanical factors such as increased intra-abdominal pressure influence further descent through the inguinal canal. The testis passes through the inguinal canal in a few days but takes about 4 wk to migrate from the external ring to the scrotum. The ovaries also descend into the pelvis from the urogenital ridge, but they do not exit from the abdominal cavity. During the last few weeks' of gestation or shortly after birth, the layers of the processus vaginalis normally fuse together and obliterate the opening from the peritoneal cavity to the inguinal canal in the area of the internal ring. The processus vaginalis also obliterates just above the testes, with the portion of the processus vaginalis that envelops the testis becoming the tunica vaginalis. In girls, the processus vaginalis obliterates earlier, at about 7 mo gestation. Failure of closure of the processus vaginalis permits fluid or abdominal viscera to escape the peritoneal cavity and accounts for a variety of inguinal-scrotal abnormalities seen in infancy and childhood (Fig. 327–1). Complete failure of obliteration of the processus predisposes to a complete inguinal hernia characterized by a protrusion of abdominal contents into the inguinal canal and possibly extending into the scrotum. Obliteration of the processus vaginalis distally (around the testis) with patency proximally results in the classic indirect inguinal hernia with the protrusion in the inguinal canal. Obliteration proximally with patency distally leads to an isolated hydrocele, also known as a scrotal hydrocele (hydrocele of the tunica vaginalis). If only fluid leaves the peritoneal cavity and enters the sac the condition is termed a *communicating* hydrocele. Obliteration of the processus vaginalis proximally and distally but patency and retained fluid in the midportion along the spermatic cord is termed a *hydrocele of the cord.* Although reasons for failure of closure of the processus vaginalis are unknown, it is more common in cases of testicular nondescent and prematurity. Persistent patency of the processus vaginalis is twice as common on the right side, presumably related to later descent of the right testis.

Pathology.

Patency of the processus vaginalis after birth is a potential hernia, but not all patients with a patent processus vaginalis will develop a clinical hernia. An indirect inguinal hernia occurs when intra-abdominal contents escape the abdominal cavity and enter the inguinal region through a patent processus vaginalis. Depending on the extent of patency of the distal processus, the hernia may be confined to the inguinal region or pass down into the scrotum.

Incidence.

The incidence of congenital indirect inguinal hernia in full-term newborn infants is 3.5–5.0%. The incidence in preterm infants is higher, ranging from 9.0–11.0%, and it approaches 30% in very low birthweight infants. Inguinal hernia is much more common among boys than girls (6:1). Sixty per cent of inguinal hernias occur on the right side, 30% are on the left side, and 10% are bilateral. Bilateral inguinal hernia is more common in premature infants, low birthweight infants, and females. There is an increased incidence of congenital inguinal hernias in twins and in individual families of patients with inguinal hernia. There is a history of another inguinal hernia in the family in 11.5% of patients.

Clinical Manifestations.

An inguinal hernia appears as a bulge in the inguinal region that extends toward and possibly into the scrotum. The bulge is most visible at times of increased intra-abdominal pressure (crying, straining, coughing). It may be present at birth or may not appear until weeks, months, or years later. The bulge is most often first noted by the parents or on routine examination by the primary physician. The classic history from the parents is of intermittent groin, labial, or scrotal swelling that spontaneously reduces but that is gradually enlarging or is more persistent and is becoming more difficult to reduce. The hallmark signs of an inguinal hernia on physical examination are a smooth, firm mass that emerges through the external

inguinal ring lateral to the pubic tubercle and enlarges with increased intra-abdominal pressure. Occasionally, an infant presents with a swelling of the scrotum without a prior bulge in the inguinal region. When the child relaxes, the hernia either reduces spontaneously or can be reduced by gentle pressure first posteriorly to free it from the external ring and then upward toward the peritoneal cavity. Methods used to demonstrate the hernia on examination vary depending on the age of the child. A quiet infant can be made to strain the abdominal

Figure 327-1 Hernia and hydroceles. (Modified from Scherer LR III, Grosfeld JL: Inguinal and umbilical anomalies. *Pediatr Clin North Am* 1993;40:1122.)

muscles by stretching out supine on the bed with legs extended and arms held straight above the head. Most infants struggle to get free, thus increasing the intra-abdominal pressure and pushing out the hernia. Older patients can be asked to perform the Valsalva maneuver by blowing up a balloon or coughing. The older child should be examined while standing; examination after voiding can also be helpful. If the bulge is located below the inguinal canal on the medial aspect of the thigh, a femoral hernia should be suspected. In the absence of a bulge, the finding of increased thickness of the inguinal canal structures on palpation will suggest the diagnosis of an inguinal hernia. Another test is the “silk glove sign,” which describes the feeling of the layers of the hernia sac (processus vaginalis) as they slide over the cord structures with rolling of the cord beneath the index finger at the pubic tubercle. It is important on examination to note the position of the testes because retractile testes are common in infants and young children and can mimic an inguinal hernia with a bulge in the region of the external ring. In the female patient, 20–25% of inguinal hernias are sliding hernias (the contents of the hernia sac are adherent within the sac and therefore not reducible); a fallopian tube or ovary may be palpated in the inguinal canal.

Occasionally, an inguinal mass appears suddenly in an infant or child and is associated with discomfort. The differential diagnosis includes incarcerated inguinal hernia, acute hydrocele of the cord, torsion of an undescended testis, and suppurative inguinal lymphadenitis. Differentiation between the incarcerated inguinal hernia and the acute hydrocele is probably the most difficult. The infant or child with an incarcerated inguinal hernia is likely to have associated findings suggestive of intestinal obstruction such as abdominal distention, vomiting, and multiple air-fluid levels evident on plain radiographs. On examination of the child with acute hydrocele, one may note that the mass is somewhat mobile. In addition, in the area between the suspected hydrocele mass and the internal ring, the cord structures may appear only slightly thickened. With the incarcerated hernia there is a lack of mobility of the groin mass as well as marked increased thickness extending from the mass up to and including the internal ring. An experienced clinician may use a bimanual examination to help differentiate groin abnormalities. The examiner palpates the internal ring per rectum with the other hand placing gentle pressure on the inguinal region over the internal ring. In cases of an indirect inguinal hernia, an intra-abdominal organ can be palpated extending through the internal ring. Another method is transillumination. It must be noted that transillumination may be misleading because the thin wall of the infants' intestine may approximate that of the hydrocele wall and both may transilluminate. This is also the reason why aspiration to determine the contents of a groin mass is discouraged.

The occurrence of suppurative adenopathy in the inguinal region can be confused with an incarcerated inguinal hernia. Examination of the drainage area of the regional inguinal lymph node may reveal a superficial infected or crusted lesion. In addition, the swelling associated with inguinal adenopathy is typically located more inferior and lateral than the mass of an inguinal hernia. There may be other associated nodes in the area. Torsion of an undescended testis may present as a painful erythematous mass in the groin. The absence of a gonad in the scrotum in the ipsilateral side should clinch this diagnosis.

An *incarcerated inguinal hernia* is one in which the contents of the sac cannot be reduced into the abdominal cavity. Contained structures can include small bowel, appendix, omentum, colon, or, rarely, Meckel diverticulum. In girls, the ovary, fallopian tube, or both are commonly incarcerated. A *strangulated hernia* is one that is tightly constricted in its passage through the inguinal canal and the hernia contents have become ischemic or gangrenous. Although incarceration may be tolerated in adults for years, most nonreducible inguinal hernias in children, unless treated, rapidly progress to strangulation with infarction of the hernia contents. Initially, there is pressure on the herniated viscera as they pass through the internal ring, inguinal canal, and external ring, leading to impaired lymphatic and venous drainage. This pressure leads to swelling of the herniated viscera, which further increases the compression in the inguinal canal, ultimately resulting in total occlusion of the arterial supply to the trapped viscera. Progressive ischemic changes take place, culminating in gangrene and/or perforation of the herniated viscera. The testis is also at risk of ischemia because of compression of the spermatic cord structures by the strangulated hernia. In girls, the ovary may herniate and become strangulated or undergo torsion. The incidence of incarceration of an inguinal hernia is between 12–17%. Two thirds of incarcerated hernias occur during the 1st yr of life. The greatest risk is in infancy, with reported incidences of between 25–30% for infants aged younger than 6 mo. The incidence of incarceration is slightly less in premature infants. The symptoms of an incarcerated hernia are irritability, pain in the groin and abdomen, and vomiting. A somewhat tense, nonfluctuant mass is present in the inguinal region and may extend down into the scrotum. The mass is well defined, may be tender, and does not reduce. With the onset of ischemic changes, the pain intensifies, and the vomiting becomes bilious or feculent. Blood may be noted in the stools. The mass typically is tender, and often there is edema and reddening of the overlying skin, with fever and signs of intestinal obstruction. The testes may be normal but also may be swollen and hard on the affected side because of venous congestion resulting from compression of the spermatic veins and lymphatic channels at the inguinal ring by the tightly strangulated hernia mass. Abdominal radiographs demonstrate features of

partial or complete intestinal obstruction, and gas within the incarcerated bowel segments may be seen below the inguinal ligament or within the scrotum. Ultrasonography may help distinguish between a hernia and a hydrocele.

Infants with *intersex problems* frequently present with inguinal hernias, often containing a gonad and requiring special consideration. Female infants with inguinal hernias, particularly if the presentation is bilateral inguinal masses, should be suspected of having testicular feminization syndrome because more than 50% of patients with testicular feminization have an inguinal hernia. Conversely, the true incidence of testicular feminization in all female infants with inguinal hernias is difficult to determine but is approximately 1%. In phenotypic females, if the diagnosis of testicular feminization is suspected, the child should be screened with a buccal smear for Barr bodies and appropriate genetic evaluation before the hernia repair. The diagnosis of testicular feminization can also be made at the time of operation by identifying an abnormal gonad (testis) within the hernia sac, by performing rectal examination to palpate a uterus, or by pelvic ultrasonography. In the normal female infant, the uterus is easily palpated as a distinct midline structure beneath the symphysis pubis on rectal examination. Preoperative diagnosis of testicular feminization syndrome or other intersex disorders such as mixed gonadal dysgenesis and selected pseudohermaphroditism enables the family to receive counseling, and gonadectomy can be accomplished at the time of the hernia repair.

Management.

The presence of an inguinal hernia in the pediatric age group constitutes the indication for operative repair. An inguinal hernia does not resolve spontaneously, and early repair eliminates the risk of incarceration and the associated potential complications, particularly in the first months of life. As many as 70% of incarcerated hernias requiring emergency operation for reduction and repair occur in the 1st yr of life. In addition, the incidence of testicular atrophy after incarceration in this setting is as high as 30%. For the routine reducible hernia, the operation should be carried out electively shortly after diagnosis. The younger the child, the more urgency with which the repair should be performed to avoid incarceration. Elective inguinal hernia repair can be safely performed in an outpatient setting with an expectation of full recovery within 48?hr. Certain conditions may dictate postponement of repair, such as marked prematurity, intercurrent pneumonia (especially respiratory syncytial virus), other infections, or severe congenital heart disease. In cases of marked prematurity, typically repair is performed before discharge home from the nursery (1800–2000?g). The operation is most often performed with the infant under general anesthesia, but it can be performed with spinal or caudal anesthesia if avoidance of intubation is preferable because of bronchopulmonary dysplasia. Preterm infants mandate special consideration because of their higher risk for apnea after general anesthesia. Preterm infants younger than 44 wk post conceptual age and full-term infants younger than 3 mo of age and with co-morbid conditions are typically observed overnight with appropriate apnea and cardiorespiratory monitors.

An incarcerated, irreducible hernia without evidence of strangulation in a clinically stable patient should initially be managed nonoperatively. Reduction by gentle compression of the hernia may be attempted. The attempt should not be continued if the infant is crying and resisting the pressure on the hernia. The use of sedation or analgesia before attempting reduction may be helpful; this reduces intra-abdominal pressure and relieves the pressure on the neck of the hernia sac at the inguinal ring. Care must be taken to avoid respiratory depression, especially in the premature infant. Other techniques advocated to assist in the nonoperative reduction of an incarcerated inguinal hernia include elevation of the lower torso and legs and brief exposure to an ice pack. Many practitioners do not favor the use of an ice pack in infants because of the risk of hypothermia. Manual reduction is performed first with traction caudad and downward to free the mass from the external inguinal ring and then upward to reduce the contents back into the peritoneal cavity. If the reduction is successful, elective repair is performed 48?hr later, by which time there is less edema, handling of the sac is easier, and the risk of complications is reduced. A common presentation in female patients is the presence of an irreducible ovary in the inguinal hernia in an otherwise asymptomatic patient. The inguinal mass is soft and nontender to gentle examination, and there is no swelling or edema and thus no findings suggestive of strangulation. This represents a “sliding” hernia with the fallopian tube and ovary fused to the posterior wall of the hernia sac. Overzealous attempts to reduce the hernia are unwarranted and potentially harmful to the tube and ovary. The risk that incarceration of the ovary in this setting will lead to strangulation is not known. Most pediatric surgeons recommend elective repair of the hernia within 48–72?hr. For any patient who presents with a prolonged history, signs of peritoneal irritation, or small bowel obstruction, surgery and operative reduction of the hernia should be performed.

OPERATIVE MANAGEMENT.

When the hernia cannot be reduced or is strangulated, immediate operation is indicated to prevent further damage to the contents of the hernia sac or testis. If there are signs of intestinal obstruction or strangulation, initial management includes nasogastric intubation, intravenous fluids, and broad-spectrum antibiotic therapy. When fluid and electrolyte imbalance has been corrected and the child's condition is satisfactory, exploration is undertaken. The operation consists of reduction of the contents of the hernia sac, separation of the hernia sac from the spermatic cord vessels and vas deferens in the inguinal canal, and high ligation of the hernia sac at the internal ring. Resection of nonviable structures within the hernia sac or of an infarcted testis may be indicated based on the experience and judgment of the surgeon.

CONTRALATERAL EXPLORATION.

Controversy exists regarding when to proceed with contralateral groin exploration in infants and children with a unilateral indirect inguinal hernia. The incidence of a contralateral patent processus vaginalis is approximately 60% at 2 mo of age and 40% at 2 yr of age. A patent processus represents only a potential hernia, and many risk factors influence the likelihood of development of an actual inguinal hernia. The advantages of contralateral exploration include avoidance of (1) parental anxiety and possibly a second anesthesia, (2) the cost of additional surgery, and (3) the risk of contralateral incarceration. The disadvantages include (1) potential injury to the spermatic cord vessels, vas deferens, and testis, (2) increased operative time, and (3) the fact that in many infants it is an unnecessary procedure. There is a chance of developing a contralateral hernia in 10–40% in children younger than 2 yr of age. In girls, because of the higher incidence of bilateral inguinal hernias and elimination of concern for injury to the spermatic cord or testis, routine contralateral exploration has been recommended up to age 5 or 6 yr. Infants and children with risk factors for development of an inguinal hernia or with medical conditions that increase the risk of anesthesia should be approached with a low threshold for routine contralateral exploration. Laparoscopy enables the assessment of the contralateral side without the risk of injury to the spermatic cord structures or testis. This procedure can be

performed through an umbilical incision or by passing a 30- or 70-degree oblique scope through the open hernia sac just before ligation of the hernia sac on the involved side. If patency of the contralateral side is demonstrated, the surgeon can proceed with bilateral hernia repair, and if the contralateral side is properly obliterated, exploration and potential complications are avoided (Figure 327–2 and Figure 327–3).

DIRECT INGUINAL HERNIA.

Direct inguinal hernias are rare in children. Direct hernias appear as groin masses that

Figure 327-2 Image on laparoscopy of patent processus vaginalis on right side.

extend toward the femoral vessels with exertion or straining. The etiology is from a muscular defect or weakness in the floor of the inguinal canal medial to the epigastric vessels. Direct inguinal hernias in children are considered an *acquired* defect. In one third of cases, the patient has a history of a prior indirect hernia repair on the side of the direct hernia, which suggests a possible injury to the floor muscles of the inguinal canal at the time of the first herniorrhaphy. In addition, patients with connective

Figure 327-3 Image on diagnostic laparoscopy of obliterated processus vaginalis on left side.

tissue disorders such as Ehlers-Danlos syndrome or Marfan syndrome are at increased risk for the development of direct inguinal hernias either independently or after indirect inguinal hernia repair. Operative repair of a direct inguinal hernia involves strengthening of the floor of the inguinal canal. Recurrence after repair, in contrast to that in adults, is extraordinarily rare. Prosthetic material for direct hernia repair or other approaches, such as preperitoneal repair, are rarely required in

the pediatric age group. The older child with a direct inguinal hernia and a connective tissue disorder may be the exception, and a prosthetic material may be useful for repair.

FEMORAL HERNIA.

Femoral hernias are rare in children. They are more common in girls than boys, with a ratio of 2:1. The bulge of a femoral hernia is located below the inguinal ligament and typically projects toward the medial aspect of the thigh. Femoral hernias are more often missed than direct hernias on physical examination or at the time of indirect hernia repair. Repair of a femoral hernia involves closure of the defect at the femoral canal, generally suturing the inguinal ligament to the pectineal ligament and pectineal fascia.

Complications.

Complications after inguinal hernia repair are uncommon. Some complications are related to technical factors (recurrence, iatrogenic cryptorchidism), whereas others are related to the underlying process, such as bowel ischemia, gonadal infarction, and testicular atrophy related to an incarcerated hernia. Wound infection occurs in less than 1%. The majority of complications are related to episodes of incarceration or occur after emergency operative reduction and hernia repair.

RECURRENT HERNIA.

The recurrence rate of inguinal hernias after elective inguinal hernia repairs is 0.5–1%, with rates as high as 2% for premature infants. The rate of recurrence after emergency repair of an incarcerated hernia is significantly higher, reported as 3–6%. In the group of patients who develop recurrent inguinal hernia, the recurrence occurs in 50% within 1 yr of the initial repair and in 75% by 2 yr.

Recurrence of an indirect hernia is most likely caused by a technical problem at the original procedure, such as failure to properly identify the sac, failure to perform high ligation of the sac at the level of the internal ring, or a tear in the sac that leaves a strip of peritoneum along the cord structures. Recurrence as a direct hernia can result from injury to the inguinal floor at the original procedure or failure to identify a direct hernia at the original exploration. Patients with connective tissue disorders or conditions that cause increased intra-abdominal pressure (ventriculoperitoneal shunts, ascites) are at increased risk for recurrence.

IATROGENIC CRYPTORCHIDISM.

Iatrogenic cryptorchidism describes malposition of the testis after inguinal hernia repair. This complication is usually related to disruption of the testicular attachment or failure to recognize an undescended testis at the original procedure, allowing the testis to retract typically to the region of the external ring. At the completion of inguinal hernia repair, the testis should be placed in a dependent intrascrotal position. If the testis will not remain in this position, an orchiopexy should be performed at the time of the hernia repair.

INCARCERATION.

Incarceration of an inguinal hernia can result in injury to the intestines, the fallopian tube and ovary, or the ipsilateral testis. Intestinal injury requiring bowel resection is uncommon, occurring in 1–2% of incarcerated hernias. In cases of incarceration in which the hernia is reduced nonoperatively, the likelihood of intestinal injury is low, but these patients should be observed closely for persistent signs and symptoms of intestinal obstruction, such as fever, vomiting, abdominal distention, or bloody stools.

The reported incidence of testicular infarction and subsequent atrophy with incarceration ranges from 4–12%, with higher rates among the irreducible cases. The testicular insult may be caused from compression of the gonadal vessels by the

incarcerated hernia mass or as a result of damage incurred during repair of a difficult incarcerated hernia. Young infants are at higher risk, with testicular infarction rates reported as high as 30% in infants younger than 2–3 mo.

INJURY TO THE VAS DEFERENS AND MALE FERTILITY.

Similar to the gonadal vessels, the vas deferens may be injured as a consequence of compression from an incarcerated hernia or during operative repair. This injury is almost certainly underreported because it is unlikely to be recognized until adulthood and even then possibly only if the injury is bilateral. One review reported an incidence of injury to the vas deferens of 1.6% based on pathology demonstrating segments of the vas deferens in the hernia sac specimen. The relationship between male fertility and previous inguinal hernia repair is also unknown. Male patients with infertility have an association of testicular atrophy and abnormal sperm counts with a previous hernia operation. There is an association in infertile males with spermatic autoagglutinating antibodies and previous inguinal hernia repair. Operative injury to the vas deferens during inguinal hernia repair may result in obstruction of the vas with diversion of spermatozoa to the testicular lymphatics; this breach of the blood-testis barrier may produce spermatic autoagglutinating antibodies.

Section 5 - *Exocrine Pancreas*

Steven L. Werlin

Excluding cystic fibrosis, diabetes mellitus, and pancreatitis, disorders of the exocrine pancreas are uncommon in childhood. Pancreatic disease may be based on traumatic, anatomic (annular pancreas, pancreas divisum), metabolic (organic acidoses, Reye syndrome, a_1 -antitrypsin deficiency), congenital (Shwachman syndrome, enzyme defects), autoimmune (diabetes mellitus), or inflammatory pathology. A comprehensive discussion of cystic fibrosis is found in Chapter 402 .

Chapter 328 - Embryology, Anatomy, and Physiology

The human pancreas develops from evaginations of primitive duodenum beginning at about the 5th wk of gestation. The larger dorsal anlage, which develops into the tail, body, and part of the head of the pancreas, grows directly from the duodenum. The smaller ventral anlage develops as one or two buds from the primitive liver and eventually forms the major portion of the head of the pancreas. At about the 17th wk of gestation, the dorsal and ventral anlagen fuse as the buds develop and the gut rotates. The ventral duct forms the proximal portion of the major pancreatic duct of Wirsung, which opens into the ampulla of Vater. The dorsal duct forms the distal portion of the duct of Wirsung and the accessory duct of Santorini, which may empty independently in about 15% of people. Variations in fusion account for pancreatic developmental anomalies. Pancreatic agenesis has been associated with a base pair deletion in the *ipf1* HOX gene, PDX1. Other genes involved in pancreatic organogenesis include the sonic hedgehog and TGF-1-beta genes.

The pancreas lies transversely in the upper abdomen between the duodenum and the spleen in the retroperitoneum. The head, which rests on the vena cava and renal vein, is adherent to the C-loop of the duodenum and surrounds the distal common bile duct. The tail of the pancreas reaches to the left splenic hilum and passes above the left kidney. The lesser sac separates the tail of the pancreas from the stomach.

By the 13th wk of gestation, exocrine and endocrine cells can be identified. Primitive acini containing immature zymogen granules are found by the 16th wk. Mature zymogen granules containing amylase, trypsinogen, chymotrypsinogen, and lipase are present at the 20th wk. Centroacinar and duct cells, which are responsible for water, electrolyte, and bicarbonate secretion, are also found by the 20th wk. The final three-dimensional structure of the pancreas consists of a complex series of branching ducts surrounded by grapelike clusters of epithelial cells. Cells containing glucagon are present at the 8th wk. Islets of Langerhans appear between the 12th and 16th wks.

328.1 Anatomic Abnormalities

Complete and partial *pancreatic agenesis* are rare conditions. Complete agenesis is associated with severe neonatal diabetes and usually death at an early age. Partial or dorsal pancreatic agenesis is often asymptomatic but may be associated with diabetes, congenital heart disease, polysplenia, and recurrent pancreatitis. Pancreatic agenesis is also associated with malabsorption

An *annular pancreas* results from incomplete rotation of the left (ventral) pancreatic anlage. Patients usually present in infancy with symptoms of complete or partial bowel obstruction. There is frequently a history of maternal polyhydramnios. Some children present with chronic vomiting, pancreatitis, or biliary colic. The treatment of choice is duodenojejunostomy. Division of the pancreatic ring is not attempted, because a duodenal diaphragm or duodenal stenosis frequently accompanies annular pancreas. Annular pancreas may be associated with Down syndrome, intestinal atresia, imperforate anus, pancreatitis, and malrotation.

Ectopic pancreatic rests in the stomach or small intestine occur in approximately 3% of the population. Most cases (70%) are found in the upper intestinal tract. Recognized on barium contrast studies by their typical umbilicated appearance, they are rarely of clinical importance. On endoscopy they are irregular, yellow nodules 2 to 4?mm in diameter. A pancreatic rest may occasionally be the lead point of an intussusception, produce hemorrhage, or cause bowel obstruction.

Pancreas divisum, which occurs in 5 to 15% of the population, is the most common pancreatic developmental anomaly. As the result of failure of the dorsal and ventral pancreatic anlagen to fuse, the tail, body, and part of the head of the pancreas drain through the small accessory duct of Santorini rather than the main duct of Wirsung. This anomaly may be associated with recurrent pancreatitis when there is relative obstruction of the outflow of the ventral pancreas. The treatment of choice of recurrent pancreatitis associated with pancreas divisum is endoscopic insertion of an endoprosthesis. If the episodes stop, surgical sphincterotomy is indicated.

Choledochal cysts are dilatations of the biliary tract and usually cause biliary tract symptoms, such as jaundice, pain, and fever. On occasion, the presentation may be pancreatitis. The diagnosis is usually easily made with ultrasonography, CT scanning, or biliary tract scan. Similarly, a choledochocele, an intraduodenal choledochal cyst, may present with pancreatitis. The diagnosis may be difficult and require endoscopic retrograde cholangiopancreatography (ERCP) or magnetic

resonance cholangiopancreatography (MRCP).

A number of rare conditions, such as *Ivemark* and *Johanson-Blizzard syndromes,* include pancreatic dysgenesis or dysfunction among their features. Many of these syndromes include renal and hepatic dysgenesis along with the pancreatic anomalies. Absence of islet cells and agenesis of the pancreas produce permanent diabetes mellitus, which begin in the neonatal period (Chapter 583).

328.2 Physiology

The acinus is the functional unit of the exocrine pancreas. Acinar cells are arrayed in a semicircle around a lumen. Ducts that drain the acini are lined by centroacinar and ductular cells. This arrangement allows the secretions of the various cell types to mix.

The acinar cell synthesizes, stores, and secretes more than 20 enzymes. These enzymes are stored in zymogen granules, some in inactive forms. The relative concentration of the various enzymes in pancreatic juice is affected and perhaps controlled by the diet, probably by regulating the synthesis of specific messenger RNA. As a general rule, diets high in fat increase the concentration of lipase; a high-protein diet increases pancreatic content of proteases; and a high-carbohydrate diet leads to increased content of amylase in the pancreatic juice. *Amylase* splits starch into maltose, isomaltose, maltotriose, and dextrins. *Trypsin* and *chymotrypsin,* both endopeptidases, and *carboxypeptidase,* an exopeptidase, are secreted by the pancreas as the inactive proenzymes trypsinogen and chymotrypsinogen. Trypsinogen is activated in the gut lumen by *enterokinase,* a brush border enzyme. Trypsin can then activate trypsinogen, chymotrypsinogen, and procarboxypeptidase into their respective active forms. Enterokinase is thus a key enzyme for exocrine pancreatic function.

Pancreatic *lipase* requires colipase, a coenzyme also found in pancreatic fluid, for activity. Lipase liberates fatty acids from the one and three positions of triglycerides, leaving two monoglycerides. The stimuli for *exocrine pancreatic secretion* are neural and hormonal. Acetylcholine mediates the cephalic phase; cholecystokinin (CCK) mediates the intestinal phase. CCK is released from the duodenal mucosa by luminal amino acids and fatty acids. Feedback regulation of pancreatic secretion is mediated by pancreatic proteases in the duodenum. Secretion of CCK is inhibited by the digestion of a trypsin-sensitive, CCK-releasing peptide released in the lumen of the small intestine or by a monitor peptide released in pancreatic fluid.

Centroacinar and duct cells secrete water and bicarbonate. Bicarbonate secretion is under feedback control and is regulated by duodenal intraluminal pH. The stimulus for bicarbonate production is *secretin* in concert with CCK. Secretin cells are abundant in the duodenum.

Although normal pancreatic function is required for digestion, maldigestion occurs only after considerable reduction in pancreatic function; lipase and colipase secretion must be decreased by 90 to 98% before fat maldigestion occurs.

Although amylase and lipase are present in the pancreas early in gestation, secretion of both amylase and lipase is low in the infant. Adult levels of these enzymes are not reached in the duodenum until late in the 1st yr of life. Digestion of the starch found in many infant formulas depends on the low levels of salivary amylase that reach the duodenum. This explains the diarrhea that may be seen in infants who are fed formulas high in glucose polymers or starch. Neonatal secretion of trypsinogen and chymotrypsinogen is at about 70% of the level found in the 1-yr-old infant. The low levels of amylase and lipase in duodenal contents of infants may be partially compensated by salivary amylase and lingual lipase. This explains the relative starch and fat intolerance of premature infants.

Chapter 329 - Pancreatic Function Tests

Pancreatic function can be measured by direct and indirect methods. Direct stimulation of the pancreas with a test (Lundh) meal of corn oil, skimmed milk powder, and dextrose or with secretin plus cholecystokinin can be performed. Classically a triple-lumen tube is used to isolate the pancreatic secretions in the duodenum. Measurement of bicarbonate concentration and enzyme activity (trypsin, chymotrypsin, lipase, and amylase) is performed on the aspirated secretions. The most commonly used test today is collection of pancreatic juice following stimulation with secretin and cholecystokinin at endoscopy. Pancreatic enzyme activities can be measured in stool. Stool trypsin has been the most commonly measured but is not as reliable as stool chymotrypsin. Neither test is as reliable as stool collection with fecal fat analysis.

A qualitative examination of the stool for *microscopic fat* globules is the most widely practiced screening test for malabsorption (also see Chapter 320). Analysis of random stool specimens by this method may give both false-positive and false-negative results. A 72-hr collection for *quantitative analysis of fat content* is preferable. The collection is usually performed at home, and the parent is asked to keep a careful dietary record, from which fat intake is calculated. A preweighed, sealable plastic container is used, which the parent keeps in the freezer. Freezing helps preserve the specimen and reduce the odor. Infants are dressed in disposable diapers with the plastic side facing the skin so that the complete sample can be transferred to the container. Normal fat absorption is greater than 93% of intake.

The elevated serum levels of trypsinogen found in neonates with cystic fibrosis form the basis of the newborn screening test being adapted in many states. With advancing pancreatic damage serum trypsinogen levels eventually fall below normal.

Pancreatic function can also be measured by *breath tests*. A labeled triglyceride, most commonly ^{14}C-triolein, is ingested and digested by pancreatic lipase in the duodenum, liberating $^{14}CO_2$, which is detected in the expired air. Because of the radioactivity and long half-life of ^{14}C, this test is not appropriate for use in children. Use of triolein labeled with ^{13}C, a stable, nonradioactive isotope, is safe for pediatric use. It has not gained widespread acceptance because detection of $^{13}CO_2$ requires a mass spectrophotometer that is not generally available.

Chapter 330 - Disorders of the Exocrine Pancreas

Disorders Associated with Pancreatic Insufficiency.

Other than cystic fibrosis, conditions that cause pancreatic insufficiency are rare in children. They include Shwachman-Diamond syndrome, isolated enzyme deficiencies, enterokinase deficiency (Chapter 320.11), chronic pancreatitis, and protein-calorie malnutrition (Chapter 320.2).

CYSTIC FIBROSIS (see Chapter 402).

Cystic fibrosis is the most common lethal genetic disease and the most common cause of malabsorption among white American children. By the end of the 1st year of life, 85–90% of children with cystic fibrosis have pancreatic insufficiency, which if untreated will lead to malnutrition in many cases. Treatment of the associated pancreatic insufficiency leads to improvement in absorption, better growth, and normalized stools. Certain mutations in the cystic fibrosis gene have been associated with idiopathic chronic pancreatitis.

SHWACHMAN-DIAMOND SYNDROME (see Chapter 121.1).

This is an autosomal recessive syndrome (1:20,000 births), consisting of pancreatic insufficiency; neutropenia, which may be intermittent; neutrophil chemotaxis defects; metaphyseal dysostosis; failure to thrive; and short stature. Patients present in infancy with poor growth and greasy, foul smelling stools that are characteristic of malabsorption. These children can be readily differentiated from those with cystic fibrosis by their normal sweat chloride levels, lack of the cystic fibrosis gene, characteristic metaphyseal lesions, and fatty pancreas on CT examination. Despite adequate pancreatic replacement therapy, poor growth frequently continues. Pancreatic insufficiency is often transient, and steatorrhea may spontaneously improve with age. The neutropenia may be cyclic. Recurrent pyogenic infections (otitis media, pneumonia, osteomyelitis, dermatitis, sepsis) are common and are a frequent cause of death. Thrombocytopenia is found in 70% of patients and anemia in 50%. Development of a myelodysplastic syndrome may occur and transformation to acute myeloid leukemia has been reported in up to 33% and 24% of patients respectively. Pathologically, the pancreatic acini are replaced by fat with little fibrosis. Islet cells and ducts are normal. The fatty pancreas has a characteristic hypodense appearance on computed tomographic and magnetic resonance scans. A candidate gene has been identified on chromosome 7.

PEARSON SYNDROME.

This is a sporadic mitochondrial DNA mutation affecting oxidative phosphorylation that manifests in infants with severe macrocytic anemia and variable thrombocytopenia. The bone marrow demonstrates vacuoles in erythroid and myeloid precursors as well as ringed sideroblasts. In addition to severe bone marrow failure, pancreatic insufficiency will contribute to growth failure. Other mitochondrial DNA mutations are associated with the development of diabetes mellitus (Kearns-Sayre, chronic progressive external ophthalmoplegia, diabetes with deafness syndromes). Mitochondrial DNA mutations are transmitted through maternal inheritance to both sexes or are sporadic.

ISOLATED ENZYME DEFICIENCIES.

Isolated deficiencies of trypsinogen, enterokinase, lipase, and colipase have been reported. Although enterokinase is a brush border enzyme, deficiency causes pancreatic insufficiency because pancreatic proteases remain inactive. Deficiencies of trypsinogen or enterokinase manifest with failure to thrive, hypoproteinemia, and edema. Isolated amylase deficiency, is typically developmental, resolving by age 2–3 ys. Amylase deficiency has not been shown to exist as a primary, permanent enzyme deficiency.

Syndromes Associated with Pancreatic Insufficiency.

Pancreatic agenesis, the *Johanson-Blizzard syndrome* (pancreatic insufficiency, deafness, low birthweight, microcephaly, midline ectodermal scalp defects, psychomotor retardation, hypothyroidism, dwarfism, absent permanent teeth, and aplasia of the alae nasae), congenital pancreatic hypoplasia, and congenital rubella are rare causes of pancreatic insufficiency. Some children with both syndromic (Alagille) and nonsyndromic paucity of intrahepatic bile ducts may also have pancreatic insufficiency associated with their liver disease. Pancreatic insufficiency has also been reported in duodenal atresia and stenosis and may also be seen in the infant with familial or nonfamilial hyperinsulinemic hypoglycemia (formerly called nesidioblastosis) who requires 95–100% pancreatectomy to control hypoglycemia.

Chapter 331 - Treatment of Pancreatic Insufficiency

Treatment of exocrine pancreatic insufficiency by oral enzyme replacement appears simple. However, in practice, although creatorrhea can usually be corrected, steatorrhea is difficult to completely correct. This is due to variability of lipase activity in different commercial preparations, inadequate dosage, incorrect timing of doses, lipase inactivation by gastric acid, and the observation that chymotrypsin in the enzyme preparation digests and thus inactivates lipase. Pancrease, Creon, and Ultrase are the preparations most widely used. These products are enteric-coated preparations that resist gastric acid inactivation.

The dosage of pancreatic replacement for children depends on the amount of food eaten and is established by trial and error. Because these products contain excess protease compared with lipase, the dosage is estimated from the lipase requirement of 500–1,500 IU/kg/meal. An adequate dose is one that is followed by the return of the stools to normal fat content, size, color, and odor. Enzyme replacement should be given at the beginning of and with the meal. Tablets should be chewed; powder can be mixed with a small quantity of food. Enzyme must also be given with snacks. Increasing enzyme supplements beyond the recommended doses not only may not improve absorption but may also retard growth and cause *fibrosing colonopathy* (see following discussion).

When adequate fat absorption is not achieved, gastric acid neutralization with an H_2 -receptor blocking agent or a proton pump inhibitor will prevent gastric acid enzyme inactivation and improve delivery of lipase into the intestine. The coating of enteric-coated preparations also protects lipase from acid inactivation.

Untoward effects secondary to pancreatic enzyme replacement therapy include allergic reactions, increased uric acid levels, and kidney stones. *Fibrosing colonopathy,* consisting of colonic fibrosis and strictures, occurs 7–12 mo following high-dose pancreatic supplement therapy (ranging from 6,500 to 58,000 IU lipase/kg/meal).

Chapter 332 - Pancreatitis

332.1 Acute Pancreatitis

Acute pancreatitis is the most common pancreatic disorder in children. Blunt abdominal injuries, mumps and other viral illnesses, multisystem disease, congenital anomalies, and biliary microlithiasis (sludging) account for most known etiologies; other causes are uncommon (Box 332–1). Many cases are of unknown etiology or are secondary to a systemic disease process. Child abuse is recognized with increased frequency as a cause of traumatic pancreatitis in young children.

Pathogenesis.

The precise sequence of events leading to pancreatitis has not been completely defined. The classic theory suggests that following an initial insult, such as ductal obstruction, lysosomal hydrolase co-localizes with pancreatic proenzymes within the acinar cell. Pancreastasis (similar in concept to cholestasis) with continued synthesis of enzymes occurs.

The pancreatic proenzymes are then activated by cathepsin leading to autodigestion, further activation and release of active proteases. Lecithin is activated by phospholipase A2 into the toxic lysolecithin. Prophospholipase is unstable and can be activated by minute quantities of trypsin. A newer theory suggests that following an insult, release of cytokines and subsequent depletion of antioxidants leads to pancreastasis and the further activation of pancreatic proenzymes. The healthy pancreas is protected by several factors: (1) the process by which pancreatic proteases are synthesized as inactive proenzymes; (2) the process by which digestive enzymes are segregated into secretory granules at pH 6.2 with low calcium concentration, which minimizes trypsin activity; (3) the presence of protease inhibitors both in the cytoplasm and zymogen granules; and (4) the process by which enzymes are secreted directly into the ducts. Histopathologically, interstitial edema appears early. Later, as the episode of pancreatitis progresses, localized and confluent necrosis, blood vessel disruption leading to hemorrhage, and an inflammatory response in the peritoneum may develop.

Clinical Manifestations.

The patient with acute pancreatitis has abdominal pain, persistent vomiting, and fever. The pain is epigastric and steady, often resulting in the child's assuming an antalgic position with hips and knees flexed, sitting upright, or lying on the side. The child is very uncomfortable and irritable and appears acutely ill. The abdomen may be distended and tender. A mass may be palpable. The pain increases in intensity for 24–48?hr, during which time vomiting may increase and the patient may require hospitalization for dehydration and may need fluid and electrolyte therapy. The prognosis for the acute uncomplicated case is excellent.

Severe acute pancreatitis is rare in children. In this life-threatening condition, the patient is acutely ill with severe nausea, vomiting, and abdominal pain. Shock, high fever, jaundice, ascites, hypocalcemia, and pleural effusions may occur. A bluish discoloration may be seen around the umbilicus (Cullen sign) or in the flanks (Grey Turner sign). The pancreas is necrotic and may be transformed into an inflammatory hemorrhagic mass. The mortality rate, which is approximately 50%, is related to the *systemic inflammatory response syndrome* with multiple organ dysfunction: shock, renal failure, acute respiratory distress syndrome, disseminated intravascular coagulation, massive gastrointestinal bleeding, and systemic or intra-abdominal infection. Also see Chapter 57.2 .

Diagnosis.

Acute pancreatitis is usually diagnosed by measurement of serum amylase and lipase activities. The serum amylase level is typically elevated for up to 4 days. A variety of other conditions may also cause hyperamylasemia without pancreatitis (Box 332–2). Elevation of salivary amylase may mislead the clinician into making the diagnosis of pancreatitis in a child with abdominal pain, but the laboratory can separate amylase isoenzymes into pancreatic and salivary fractions. Initially, serum amylase levels are normal in 10–15% of patients. Serum lipase is more specific than amylase for acute inflammatory pancreatic disease and should be determined when pancreatitis is suspected and the amylase level is normal. The serum lipase typically remains elevated 8–14 days longer than serum amylase. Serum lipase may also be elevated in nonpancreatic diseases.

Other laboratory abnormalities that may be present in acute pancreatitis include hemoconcentration, coagulopathy, leukocytosis,

CMV = cytomegalovirus; HIV = human immunodeficiency virus; EBV = Epstein-Barr virus.

hyperglycemia, glucosuria, hypocalcemia, elevated gamma glutamyl transpeptidase, and hyperbilirubinemia.

Roentgenography of the chest and abdomen may demonstrate nonspecific findings. The chest roentgenogram may demonstrate platelike atelectasis, basilar infiltrates, elevation of the hemidiaphragm, left- (rarely right-) sided pleural effusions, pericardial effusion, and pulmonary edema. Abdominal roentgenograms may demonstrate a sentinel loop, dilatation of the transverse colon (cutoff sign), ileus, pancreatic calcification (if recurrent), blurring of the left psoas margin, a pseudocyst, diffuse abdominal haziness (ascites), and peripancreatic extraluminal gas bubbles.

Ultrasound and *computed tomography* (*CT) scanning* have major roles in the diagnosis and follow-up of children with pancreatitis. Findings may include pancreatic enlargement, a hypoechoic, sonolucent edematous pancreas, pancreatic masses, fluid collections, and abscesses (Fig. 332–1); at least 20% of children with acute pancreatitis initially have normal imaging studies. Endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) are essential in the investigation of recurrent pancreatitis, pancreas divisum, sphincter of Oddi dysfunction, and disease associated with gallbladder pathology. Endoscopic ultrasonography helps visualize the pancreaticobiliary system.

Treatment.

The aims of medical management are to relieve pain and restore metabolic homeostasis. Analgesia should be given in adequate doses. Fluid, electrolyte, and mineral balance should be restored and maintained. Nasogastric suction is useful in patients who are vomiting. While vomiting, the patient should be maintained with nothing by mouth. Prophylactic antibiotics are useful in severe cases to prevent infected pancreatic necrosis. The response to treatment is usually complete over 2–5 days. Refeeding may commence when vomiting has resolved, the serum amylase is falling, and clinical symptoms are resolving.

The treatment of severe acute pancreatitis may involve enteral or total parenteral nutrition, antibiotics, gastric acid suppression and peritoneal lavage to reduce the risk of secondary infection. Endoscopic therapy may be of benefit when pancreatitis is caused by anatomic abnormalities, such as strictures or stones. Surgical therapy of acute pancreatitis is rarely required, but may include drainage of necrotic material or abscesses.

Prognosis.

Children with uncomplicated acute pancreatitis do well and recover over a period of 2–5 days. When pancreatitis is associated with trauma or systemic disease, the prognosis is typically

Figure 332.1-1 Acute pancreatitis. Computed tomography (CT) through the body of the pancreas demonstrates a halo of decreased attenuation around the pancreas that represents a peripancreatic zone of edema and fluid *(curved arrows)*. Note the pancreatic ascites most obvious lateral to the liver *(small arrows)*. If intravenous contrast was administered before the CT scan, the inflamed pancreas would appear more dense (whiter). (L = liver; A = aorta; K = kidney; S = spleen; IVC = inferior vena cava; ST = stomach.) (From Freeny P, Lawson T: The pancreas. In Putman CE, Ravin CE [editors]: *Textbook of Diagnostic Imaging*. Philadelphia, WB Saunders, 1988.)

related to the associated medical conditions. Prognostic systems widely used in adults such as *Ranson's criteria* and the *APACHE score* are inappropriate for use in children. Measurement of urinary trypsin activation peptide (TAP), the amino terminus peptide split when trypsinogen is activated to trypsin, and activation peptide of carboxypeptidase B (CAPAP), which may be the most sensitive diagnostic tests for determining the severity of an episode of acute pancreatitis, are under study and have not been evaluated in children. **REFERENCES**

332.2 Chronic Pancreatitis

Chronic, relapsing pancreatitis in children is frequently hereditary or due to congenital anomalies of the pancreatic or biliary ductal system. Hereditary pancreatitis (HP) is transmitted as an autosomal dominant trait with incomplete penetrance but variable expressivity. Symptoms frequently begin in the first decade but are usually mild at the onset. Although spontaneous recovery from each attack occurs in 4–7 days, episodes become progressively severe. HP may be clinically diagnosed by the presence of the disease in successive generations of a family. An evaluation during symptom-free intervals may be unrewarding until calcifications,

pseudocysts, or pancreatic insufficiency develop. The gene for HP has been cloned and mapped to the cationic trypsinogen gene on the long arm of chromosome 7. Multiple mutations of the HP gene associated with hereditary pancreatitis have been described. The pathophysiology of HP is unclear. One theory states that cationic trypsinogen has a tendency to autoactivate but has a trypsin-sensitive cleavage site. Loss of this cleavage site in the abnormal protein permits autodigestion of the pancreas. The other theory states that mutated cationic trypsinogen autoactivates at a faster rate than normal trypsinogen. Mutations of other genes including *cystic fibrosis* gene *(CFTR,)* typically in the 5T promoter region, and the *SPINK 1* gene *(pancreatic trypsin inhibitor)* have also been associated with recurrent or chronic pancreatitis.

Other conditions associated with chronic, relapsing pancreatitis are hyperlipidemia (types I, IV, and V), hyperparathyroidism, and ascariasis. In the past most cases of recurrent pancreatitis in childhood were considered idiopathic; however, with the discovery of at least three gene families associated with recurrent pancreatitis, this will probably change. Congenital anomalies of the ductal systems, such as pancreas divisum, are probably more common than previously recognized.

A thorough diagnostic *evaluation* of every child with more than one episode of pancreatitis is indicated. Serum lipid, calcium, and phosphorus levels are determined. Stools are evaluated for *Ascaris,* and a sweat test is performed. Evaluation of the HP, SPINK 1, and the CFTR genes is performed. Plain abdominal films are evaluated for the presence of pancreatic calcifications. Abdominal ultrasound or CT scanning is performed to detect the presence of a pseudocyst. The biliary tract is evaluated for the presence of stones.

ERCF and *MRCF* are techniques that can be used to define the anatomy of the gland and are mandatory whenever surgery is considered. One of these studies should be performed as part of the evaluation of any child with idiopathic, nonresolving, or recurrent pancreatitis and in patients with a pseudocyst before surgery. In these cases, ERCP or MRCP may detect a previously undiagnosed anatomic defect that may be amenable to endoscopic or surgical therapy. Endoscopic treatments include sphincterotomy, stone extraction, and insertion of pancreatic or biliary endoprostheses. These treatments allow for successful nonsurgical management of conditions previously requiring surgical intervention. As more experience is gained, MRCP may supplement or replace ERCP.

Chapter 333 - Pseudocyst of the Pancreas

Pancreatic pseudocyst formation is an uncommon sequela to acute or chronic pancreatitis. Pseudocysts are sacs delineated by a fibrous wall in the lesser peritoneal sac. They may enlarge or extend in almost any direction, thus producing a wide variety of symptoms (Fig. 333–1).

A pancreatic pseudocyst is suggested when an episode of pancreatitis fails to resolve or when a mass develops after an episode of pancreatitis. Clinical features usually include pain, nausea, and vomiting. The most common signs are a palpable mass in 50% of patients and jaundice in 10%. Other findings include ascites and pleural effusions (usually left-sided).

The most useful diagnostic techniques are ultrasonography, computed tomography (CT) scanning, endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP). Because of its ease, availability, and reliability, ultrasonography is the first choice. Sequential ultrasonography studies have demonstrated that most small pseudocysts (<6?cm) resolve spontaneously. It is recommended that the patient with acute pancreatitis undergo an ultrasonographic evaluation 2–4 wk after resolution of the acute episode for an evaluation of possible pseudocyst formation.

The treatment for nonresolving, symptomatic pseudocysts used to be surgery. Now percutaneous and endoscopic drainage

Figure 333-1 Pseudocyst. Follow-up computed tomographic scan 5 mo after the episode of acute pancreatitis demonstrates a large pseudocyst (PC). This large pseudocyst will probably not resolve spontaneously and may need drainage. (From Freeny P, Lawson T: The pancreas. In Putman CE, Ravin CE [editors]: *Textbook of Diagnostic Imaging*. Philadelphia, WB Saunders, 1988.)

of pseudocysts have replaced surgical drainage except for complicated or recurrent pseudocysts. A pseudocyst must be allowed to mature for 4–6 wk before surgical drainage is attempted; percutaneous or endoscopic drainage may be attempted earlier. ERCP or MRCP should precede surgical treatment to help the surgeon plan the approach and define anatomic abnormalities. **REFERENCES**

Chapter 334 - Pancreatic Tumors

Neoplasia.

Pancreatic tumors may be of either endocrine or nonendocrine origin. Tumors of endocrine origin include *insulinomas* and *gastrinomas*. These and other functioning tumors occur in the autosomal dominantly inherited multiple endocrine neoplasia type 1 (MEN-1). Hypoglycemia accompanied by higher than expected (for serum glucose) insulin levels or refractory gastric ulcers (Zollinger-Ellison syndrome) indicate the possibility of a pancreatic tumor (see Chapter 326). Most gastrinomas arise outside the pancreas. The treatment of choice is surgical removal. If the primary tumor cannot be found or if it has metastasized, cure may not be possible. Treatment with a proton pump inhibitor to inhibit gastric acid secretion is then indicated. Gastrectomy is no longer recommended.

The *watery diarrhea–hypokalemia–acidosis syndrome* is usually produced by the secretion of vasoactive intestinal peptide (VIP) by a non-a-cell tumor (VIPoma) (see Table 326–2). VIP levels are frequently, but not always, increased in the serum. Treatment is surgical removal of the tumor. When this is not possible, symptoms may be controlled by the use of octreotide acetate (cyclic somatostatin, Sandostatin), a synthetic

analog of somatostatin. Pancreatic tumors secreting a variety of hormones, including glucagon, somatostatin, and pancreatic polypeptide, have also been described.

Pancreatoblastomas, pancreatic adenocarcinomas, cystadenomas, and rhabdomyosarcomas are rarely encountered. Peculiar to childhood are *pancreatoblastomas*, which are embryonal tumors that secrete a-fetoprotein and may contain both endocrine and exocrine elements. Their clinical behavior is malignant but not well characterized owing to their rarity. Presurgical chemotherapy should be considered for lesions not primarily resectable. Resection can be curative; adjuvant chemotherapy has been used, but its effectiveness is not established. Carcinoma of the exocrine pancreas is a major problem in adults, accounting for 2% of diagnoses and 5% of deaths due to cancer. It is very rare in childhood. No definite causes are known. Several genetic syndromes including hereditary pancreatitis and MEN-1 lead to an increased incidence of pancreatic cancer in adult life. The *Frantz tumor* is a papillary cystic tumor that is usually found in girls and young women. Presenting symptoms are usually abdominal pain, mass, or jaundice. The treatment of choice is total surgical removal.

Insulinomas and persistent hyperinsulinemic hypoglycemia of infancy (nesidioblastosis) produce symptomatic hypoglycemia. Massive subtotal or total pancreatectomy is the treatment of choice when medical treatment fails (Chapter 81). These children may then develop pancreatic insufficiency and diabetes as a complication of treatment.

Cysts of the pancreas occur in von Hippel-Lindau disease. Solid and cystic papillary tumors mimic pancreatic ontogeny. Their natural history is still being determined. Metastases have been reported, but adjuvant therapy following surgical excision cannot yet be recommended.

The diagnosis is suggested by CT scanning. Surgery is the only known effective therapy. Prognosis is good for completely resected endocrine tumors but very poor for carcinomas, even with extensive surgery. Children who survive partial or complete pancreatectomy may have decreased pancreatic exocrine and endocrine reserve.

Section 6 - *The Liver and Biliary System*

Chapter 335 - Development and Function of the Liver and Biliary System Michael D. Bates and

William F. Balistreri

During the early embryonic process of gastrulation, the three embryonic germ layers (endoderm, mesoderm, and ectoderm) are formed. The liver and biliary system arise from cells of the ventral foregut endoderm; their development can be divided into three distinct processes (Fig. 335–1). First, through unknown mechanisms, ventral foregut endoderm acquires *competence* to receive signals arising from the cardiac mesoderm. These mesodermal signals, in the form of various fibroblast growth factors and bone morphogenetic proteins, result in *specification* of cells that will form the liver and activation of liver-specific genes. This specification occurs in animal models just before visible budding of the liver. These newly specified cells then migrate in a cranial ventral direction into the septum transversum in the 4th wk of gestation to initiate liver *morphogenesis*. The growth and development of the newly budded liver requires interactions with endothelial cells. Proteins that are important for mammalian liver development are listed in Table 335–1 .

Within the ventral mesentery, proliferation of migrating cells form anastomosing hepatic cords, with the network of primitive liver cells, sinusoids, and septal mesenchyme establishing the basic architectural pattern of the liver lobule (Fig. 335–2). The solid *cranial* portion of the hepatic diverticulum (pars hepatis) eventually forms the hepatic parenchyma and the intrahepatic bile ducts; the *caudal* portion (pars cystica) becomes the gallbladder, cystic duct, and common bile duct. The hepatic lobules are identifiable in the 6th gestational wk. The bile canalicular structures that include microvilli and junctional complexes are specialized loci of the liver cell membrane; these appear very early in gestation; by 6–7 wk large canaliculi bounded by several hepatocytes are seen. The intrahepatic bile ducts are derived through branching and remodeling of the hepatic duct; formation is complete by the 3rd mo. The cystic duct and the gallbladder are fully recanalized by the 7th–8th wk (see Fig. 335–2*C*).

In the hepatic excretory (biliary) system, intercellular bile canaliculi empty into the smallest bile ductules, which unite to form interlobular bile ducts that follow the terminal branches of the portal vein. At the hilum of the liver, the intrahepatic ducts leave the branches of the portal vein and merge to form the extrahepatic biliary system. The ducts of the right and left lobes form the common hepatic duct. The common bile duct is formed from the merger of the common hepatic duct and cystic duct; it extends along the right edge of the lesser omentum, terminating as the intramural papilla of Vater. Union of the biliary tract with the pancreatic ducts forms the ampulla of Vater, which, with the sphincter of Oddi, regulates the flow of bile into the intestine, prevents entry of bile into the pancreatic duct, and inhibits reflux of intestinal contents into the ducts.

Fetal hepatic blood flow is derived from the hepatic artery and from the portal and umbilical veins, which form the portal sinus. The portal venous inflow is directed mainly to the right lobe of the liver; umbilical flow is primarily to the left. The ductus venosus shunts blood from the portal and umbilical veins to the hepatic vein, bypassing the sinusoidal network. The ductus venosus becomes obliterated when oral feedings are initiated. The oxygen saturation is lower in portal than in umbilical venous blood; accordingly, the right hepatic lobe has lower

Figure 335-1 Processes involved in early liver development. *A*, The ventral foregut endoderm acquires competence to receive signals arising from the cardiac mesoderm. *B*, Specific cells of the ventral foregut endoderm undergo *specification* and activation of liver-specific genes under the influence of mesodermal signals. *C*, The newly specified cells migrate into the septum transversum to initiate liver *morphogenesis*. (Reprinted from Zaret KS: Liver specification and early morphogenesis. Mech Dev 2000;92:83–88, with permission. ©2000.)

oxygenation and greater hematopoietic activity than the left hepatic lobe. The fetal sinusoidal endothelium is the site of large macrophages, which become the Kupffer (reticuloendothelial) cell network.

The transport and metabolic activities of the liver are facilitated by the structural arrangement of liver cell cords, which are formed by rows of hepatocytes, separated by sinusoids that converge toward the tributaries of the hepatic vein (the central vein) located in the center of the lobule (see Fig. 335–2*D*). This establishes the pathways and patterns of flow for substances to and from the liver. In addition to arterial input from the systemic circulation, the liver also receives venous input from the

gastrointestinal tract via the portal system. The products of the hepatobiliary system are released by two different paths: through the hepatic vein, and through the biliary system back into the intestine. Plasma proteins and other plasma components

Figure 335-2 Hepatic morphogenesis. *A*, Ventral outgrowth of hepatic diverticulum from foregut endoderm in the 3.5-wk embryo. *B*, Between the two vitelline veins, the enlarging hepatic diverticulum buds off epithelial (liver) cords that become the liver parenchyma, around which the endothelium of capillaries (sinusoids) align (4-wk embryo). *C*, Hemisection of embryo at 7.5 wk demonstrating recanalization of the biliary tract. *D*, Three-dimensional representation of the hepatic lobule as present in the newborn. are secreted by the liver. Absorbed and circulating nutrients arrive through the portal vein or the hepatic artery and pass through the sinusoids and past the hepatocytes to the systemic circulation at the central vein. Biliary components are transported via the series of enlarging channels from the bile canaliculi through the bile ductule to the common bile duct.

Bile secretion has been noted at the 12th gestational wk. The major components of bile vary with stage of development. Near term, cholesterol and phospholipid content is relatively low; low concentrations of bile acids, the absence of bacterially derived (secondary) bile acids, and the presence of unusual bile acids reflect low rates of bile flow and immature bile acid synthesis.

The liver reaches a peak relative size at the 9th wk at about 10% of the fetal weight. Early in development, the liver is the primary site of hematopoiesis; during the 7th wk, hematopoietic cells outnumber functioning hepatocytes in the hepatic anlage. These early hepatocytes are smaller than at maturity (~20?µm vs. 30–35?µm) and contain less glycogen. Near term, the hepatocyte mass expands to dominate the organ, as cell size and glycogen content increase. Hematopoiesis is virtually absent by the 2nd postnatal month in full-term infants. As the density of hepatocytes increases with gestational age, the relative volume of the sinusoidal network decreases. The liver constitutes 5% of body weight at birth but only 2% in an adult.

Several metabolic processes are immature in a healthy newborn infant, owing in part to the fetal patterns of activity of various enzymatic processes. Many hepatic functions are carried out for a fetus by the maternal liver, which provides nutrients and serves as a route of elimination of metabolic end products and toxins. Fetal liver metabolism is devoted primarily to the production of proteins for growth requirements. Toward term, primary functions become production and storage of essential nutrients, excretion of bile, and establishment of processes of elimination. Extrauterine adaptation requires de novo enzyme synthesis. Modulation of these processes depends on substrate and hormonal input via the placenta and on dietary and hormonal input in the postnatal period.

HEPATIC ULTRASTRUCTURE

Hepatocytes exhibit various ultrastructural features that reflect their biologic functions

(Fig. 335–3). First, hepatocytes, like other epithelial cells, are polarized; their structure and function are directionally oriented. One result of this polarity is that various regions of the hepatocyte plasma membrane exhibit specialized functions. Bidirectional transport can occur at the sinusoidal surface, where materials reaching the liver via the portal system enter and compounds secreted by the liver leave the hepatocyte. Canalicular membranes of adjacent hepatocytes form bile canaliculi, which are bounded by tight junctions preventing transfer of secreted compounds back into the sinusoid. Within hepatocytes, a number of different cell organelles are the sites of hepatic metabolic and synthetic activity. Abundant mitochondria are the sites of oxidation and metabolism of heterogeneous classes of substrates, of fatty acid oxidation, of key processes in gluconeogenesis, and of storage and release of energy. The endoplasmic reticulum, a continuous network of rough- and smooth-surfaced tubules and cisternae, is the site of various processes, including protein and triglyceride synthesis and drug metabolism. The endoplasmic reticulum is the major component of the microsomal fraction obtained by ultracentrifugation of liver homogenate. Low fetal activity of microsomal-bound enzymes accounts for a relative inefficiency of xenobiotic (drug) metabolism. The Golgi apparatus is active in protein packaging and possibly in bile secretion. Hepatocyte peroxisomes are single-membrane-limited cytoplasmic organelles that contain enzymes such as oxidases and catalase and those that have a role in lipid and bile acid metabolism. Lysosomes

Figure 335-3 Schematic view of the ultrastructure and organelles of hepatocytes. (Reprinted from Sherlock S: Hepatic cell structure. In Sherlock S [editor]: *Diseases of the Liver and Biliary System*, 6th ed. Oxford, Blackwell Scientific, 1981, p 10, with permission from Blackwell Scientific.)

contain numerous hydrolases that have a role in intracellular digestion. The hepatocyte cytoskeleton, composed of actin and other filaments, is distributed throughout the cell and concentrated near the plasma membrane. Microfilaments and microtubules may have a role in receptor-mediated endocytosis, in bile secretion, and in maintaining the architecture and motility of the cell.

METABOLIC FUNCTIONS OF THE LIVER

Carbohydrate Metabolism.

The liver regulates serum glucose levels closely. The liver stores excess carbohydrate as glycogen, a polymer of glucose readily hydrolyzed to glucose during fasting. To maintain serum glucose, hepatocytes produce free glucose by either gluconeogenesis or glycogenolysis. Gluconeogenic activity is present in the fetal liver but increases rapidly after birth. Immediately after birth, an infant is dependent on hepatic glycogenolysis; thereafter, an infant is capable of both glycogenolysis and gluconeogenesis. Fetal glycogen synthesis begins at about the 9th wk of gestation, with glycogen stores most rapidly accumulated near term, when the liver contains two to three times the amount of glycogen of adult liver. Most of this stored glycogen is used in the immediate postnatal period. Reaccumulation is initiated at about the 2nd wk of postnatal life, and glycogen stores reach adult levels at approximately the 3rd wk in healthy full-term infants. The fluctuations in serum glucose levels in preterm infants are due in part to the fact that efficient regulation of the synthesis, storage, and degradation of glycogen develops only near the end of full-term gestation. Dietary carbohydrates such as galactose are converted to glucose, but there is a substantial dependence on gluconeogenesis during fasting for glucose in early life, especially if glycogen stores are limited.

Protein Metabolism.

During the rapid fetal growth phase, specific decarboxylases that are rate-limiting in the biosynthesis of physiologically important polyamines have higher activities than in the mature liver. The rate of synthesis of albumin and secretory proteins in the developing liver parallels the quantitative changes in endoplasmic reticulum. Synthesis of albumin appears at approximately the 7th–8th wk in a human fetus and increases in inverse proportion to that of a-fetoprotein, which is a dominant early fetal protein. By the 3rd–4th mo of gestation, the fetal liver is able to produce fibrinogen, transferrin, and low-density lipoproteins. From this period on, fetal plasma contains each of the major protein classes, at concentrations considerably below those achieved at maturity.

The *postnatal* patterns of development of various proteins are heterogeneous. Lipoproteins of each class rise abruptly in the 1st wk after birth to reach levels that vary little until puberty. Albumin concentrations are low in a neonate (~2.5?g/dL), reaching adult levels (~3.5?g/dL) after several months. Levels of ceruloplasmin and complement factors increase slowly to adult values during the first year. In contrast, transferrin levels at birth are similar to those of an adult, decline for 3–5 mo, and rise thereafter to achieve their final concentrations. Low levels of activity of specific proteins have implications for the nutrition of an infant; for example, a low level of cystathionine ?-lyase (cystathionase) activity impairs the trans-sulfuration pathway by which dietary methionine is converted to cysteine; accordingly, the latter must be supplied exogenously. Similar dietary requirements may exist for other sulfur-containing amino acids, such as taurine.

Lipid Metabolism.

Fatty acid oxidation provides a major source of energy in early life, complementing glycogenolysis and gluconeogenesis. Newborn infants are relatively intolerant of prolonged fasting, owing in part to a restricted capacity for hepatic ketogenesis. Rapid maturation of the ability of the liver to oxidize fatty acid occurs during the 1st few days of life. Milk provides the major source of calories in early life; this high-fat, low-carbohydrate diet mandates active gluconeogenesis to maintain blood sugar levels. When the glucose supply is limited, ketone body production from endogenous fatty acids may provide energy for hepatic gluconeogenesis and an alternative fuel for brain metabolism. When carbohydrates are in excess, the liver produces triglycerides. Metabolic processes involving lipids and lipoprotein are predominantly hepatic; liver immaturity or disease affects lipid concentrations and lipoproteins.

Biotransformation.

Newborn infants have a decreased capacity to metabolize and detoxify certain drugs, owing to underdevelopment of the hepatic microsomal component that is the site of

the specific oxidative, reductive, hydrolytic, and conjugation reactions required for these biotransformations. The major components of the mono-oxygenase system, such as cytochrome P_{450} , the reduced form of nicotinamide-adenine dinucleotide phosphate, and cytochrome c reductase, are present in low concentrations in fetal microsomal preparations. In full-term infants, hepatic uridine diphosphate (UDP) glucuronosyltransferase and enzymes involved in the oxidation of polycyclic aromatic hydrocarbons have very low activities. Age-related differences in pharmacokinetics vary. For example, the half-life of acetaminophen in a newborn is similar to that of an adult, whereas theophylline has a half-life of approximately 100?hr in a premature infant, as compared to 5–6?hr in an adult. These differences in metabolism as well as factors such as binding to plasma proteins and renal clearance determine appropriate drug dosage to avoid toxicity. Dramatic examples of the susceptibility of newborn infants to drug toxicity are the responses to chloramphenicol ("gray baby" syndrome) or to benzoyl alcohol and its metabolic products, which involve ineffective glucuronide and glycine conjugation, respectively. The low concentrations of antioxidants (vitamin E, superoxide dismutase, and glutathione peroxidase) in the fetal and early newborn liver lead to increased susceptibility to deleterious effects of oxygen toxicity and oxidant injury through lipid peroxidation.

Conjugation reactions (which convert drugs or metabolites into forms that can be eliminated in bile) are also catalyzed by hepatic microsomal enzymes. Newborn infants have decreased activity of UDP glucuronosyltransferase, which converts unconjugated bilirubin to the readily excreted glucuronide conjugate and is the rate-limiting enzyme in the excretion of bilirubin. There is rapid postnatal development of transferase activity, even in prematurely born infants, irrespective of gestational age; this suggests that birth-related rather than age-related factors are of primary importance in the postnatal development of activity of this enzyme. Microsomal activity can be stimulated by administration of phenobarbital, rifampin, or other inducers of cytochrome P_{450} . Alternatively, drugs such as cimetidine may inhibit microsomal P_{450} activity.

Hepatic Excretory Function.

Hepatic excretory function and bile flow are closely related to bile acid excretion and recirculation. Bile acids are the major product of degradation of cholesterol. Their incorporation into mixed micelles with cholesterol and phospholipid creates an efficient vehicle for solubilization and intestinal absorption of lipophilic compounds, such as dietary fats and fat-soluble vitamins. Secretion of bile acids is the major determinant of bile flow in the mature animal. Accordingly, maturity of bile acid metabolic processes affects overall hepatic excretory function, including biliary excretion of endogenous and exogenous compounds.

In humans, the two primary bile acids, cholic acid and chenodeoxycholic acid, are synthesized in the liver. Before excretion, they are conjugated with glycine and taurine. In response to a meal, contraction of the gallbladder delivers bile acids to the intestine to assist in fat digestion and absorption. After mediating fat digestion, the bile acids themselves are reabsorbed from the terminal ileum through specific active transport processes.

Box 335-1. Causes of Impaired Bile Acid Metabolism and Enterohepatic Circulation

DEFECTIVE BILE ACID SYNTHESIS/TRANSPORT

- Inborn errors of bile acid synthesis: reductase deficiency, isomerase deficiency
- Intrahepatic cholestasis (neonatal hepatitis)
- Progressive familial intrahepatic cholestasis (PFIC)
- Acquired defects in bile acid synthesis secondary to severe liver disease

ABNORMALITIES OF BILE ACID DELIVERY TO THE BOWEL

- Celiac sprue (sluggish gallbladder contraction)
- Extrahepatic bile duct obstruction (biliary atresia)

LOSS OF ENTEROHEPATIC CIRCULATION OF BILE ACIDS

- External bile fistula
- Cystic fibrosis Contaminated small bowel syndrome (with bile acid precipitation, increased jejunal absorption, and "short circuiting")
- Drug-induced entrapment of bile

Cystic fibrosis Contaminated small bowel syndrome (with bile acid precipitation, increased jejunal absorption, and "short circuiting")

Drug-induced entrapment of bile acids in intestinal lumen (cholestyramine)

BILE ACID MALABSORPTION

Primary bile acid malabsorption (absent or inefficient ileal active transport)

Secondary bile acid malabsorption

- Ileal disease or resection
- Cystic fibrosis

DEFECTIVE UPTAKE OR ALTERED INTRACELLULAR METABOLISM

Parenchymal disease (acute hepatitis, cirrhosis)

Regurgitation from cells

Portosystemic shunting

Cholestasis

They return to the liver via portal blood, are taken up by liver cells, and are re-excreted in bile. In an adult, this enterohepatic circulation involves 90–95% of the circulating bile acid pool. Bile acids that escape ileal reabsorption reach the colon, where the bacterial flora, through dehydroxylation and deconjugation, produces the secondary bile acids, deoxycholate and lithocholate. In an adult, the composition of bile reflects the excretion of the primary and also the secondary bile acids, which are reabsorbed from the distal intestinal tract.

Neonates have inefficient ileal bile acid reabsorption and a low rate of hepatic clearance of bile acids from portal blood. The latter results in elevated serum concentrations of bile acids in healthy newborns, often to levels that would suggest liver disease in older individuals. The size of the bile acid pool in a neonate is about half that of an adult, and the bile acid concentration in the proximal intestinal lumen is similarly decreased to levels that are frequently below the concentration required for micelle formation (2?mM); accordingly, absorption of dietary fats and fat-soluble vitamins is reduced but not sufficiently to produce malabsorption. Transient phases of "physiologic cholestasis" and "physiologic steatorrhea" have a role in the nutrition of low birthweight infants but are of minor importance to healthy full-term newborns.

Beyond the neonatal period, disturbances in bile acid metabolism may be responsible for diverse effects on hepatobiliary and intestinal function (Box 335–1).

Chapter 336 - Manifestations of Liver Disease

Vicky Lee Ng
William Balistreri

Pathologic Manifestations.

Alterations in hepatic structure and function can be *acute* or *chronic,* with varying patterns of reaction of the liver to cell injury. Hepatocyte injury may result in inflammation or cell death (necrosis), which may be followed by a healing process of scar formation (fibrosis), and potentially nodule formation (regeneration). Cirrhosis is the end result of virtually any progressive liver disease.

Inflammation or necrosis, or both, of individual hepatocytes can result from viral infection, drugs or toxins, hypoxia, immunologic disorders, or inborn errors of metabolism. The evolving process leads to repair, continuing injury with chronic changes, or in rare cases to massive hepatic damage.

Cholestasis is an alternative or concomitant response to injury caused by extrahepatic or intrahepatic obstruction to bile flow. Accumulation in serum of substances normally excreted in bile such as direct-reacting bilirubin, cholesterol, bile acids, and trace elements occurs. Bile pigment in liver parenchyma can be seen in a liver biopsy specimen. In extrahepatic obstruction, bile pigment may be visible in the intralobular bile ducts or throughout the parenchyma as bile lakes or infarcts. In intrahepatic cholestasis, an injury to hepatocytes or an alteration in hepatic physiology leads to a reduction in the rate of secretion of solute and water. Likely causes include alterations in (1) ultrastructure or cytoskeleton of the hepatocyte; (2) organelles responsible for bile secretion; (3) enzymatic or transporter activity; or (4) permeability of the bile canalicular apparatus. The end result may be clinically indistinguishable from obstructive cholestasis.

Cirrhosis, defined histologically by the presence of bands of fibrous tissue that link central and portal areas and form parenchymal nodules, is a potential end stage of any acute or chronic liver disease. Cirrhosis may be posthepatitic (after acute or chronic hepatitis) or postnecrotic (after toxic injury), or it may follow chronic biliary obstruction (biliary cirrhosis). Cirrhosis may be **macronodular,** with nodules of various sizes (up to 5?cm) separated by broad septa, or **micronodular,** with nodules of uniform size (<1?cm) separated by fine septa. Mixed forms also occur. The progressive scarring of cirrhosis results in altered hepatic blood flow, with further impairment of liver cell function. In addition, the increased intrahepatic resistance to portal blood flow leads to portal hypertension.

Primary tumors of the liver are discussed in Chapter 496 . The liver may be **secondarily** involved in neoplastic (metastatic) and non-neoplastic (storage diseases and fat infiltration) processes as well as a number of systemic conditions and infectious processes. The liver may also be affected by chronic passive congestion or acute hypoxia, with hepatocellular damage.

Clinical Manifestations

HEPATOMEGALY.

Enlargement of the liver can be due to several mechanisms (Box 336–1). Concepts of normal liver size have been based on age-related clinical indices, such as (1) the degree of extension of the liver edge below the costal margin;

Box 336-1. Mechanisms of Hepatomegaly

INCREASE IN THE NUMBER OR SIZE OF THE CELLS IN THE LIVER

Storage

Fat: malnutrition, obesity, metabolic liver disease (e.g., diseases of fatty acid oxidation and Reye syndrome–like illnesses), lipid infusion (total parenteral nutrition), cystic fibrosis, diabetes mellitus, medication related, pregnancy

Specific lipid storage diseases: Gaucher, Niemann-Pick, Wolman disease

Glycogen: glycogen storage diseases (multiple enzyme defects); total parenteral nutrition; infant of diabetic mother, Beckwith syndrome

Miscellaneous: a_1 -antitrypsin deficiency, Wilson disease, hypervitaminosis A, neonatal iron storage disease

INFLAMMATION

Hepatocyte enlargement (hepatitis)

Viral—acute and chronic

Bacterial—sepsis, abscess, cholangitis

- Hepatocyte enlargement (hepatitis)
  - Viral—acute and chronic
  - Bacterial—sepsis, abscess, cholangitis
  - Toxic—drugs
- Kupffer cell enlargement
- Autoimmune
  - Chronic hepatitis
  - Sarcoidosis
  - Systemic lupus erythematosus
  - Sclerosing cholangitis

INFILTRATION

- Primary liver tumors
  - Benign
    - Hepatocellular
      - Focal nodular hyperplasia
      - Nodular regenerative hyperplasia
      - Hepatocellular adenoma
    - Mesodermal
      - Infantile hemangioendothelioma
      - Mesenchymal hamartoma
    - Cystic masses
      - Choledochal cyst
      - Hepatic cyst
      - Hematoma
      - Parasitic cyst
      - Pyogenic or amebic abscess
  - Malignant
    - Hepatocellular
      - Hepatoblastoma
      - Hepatocellular carcinoma
    - Mesodermal
      - Angiosarcoma
      - Undifferentiated embryonal sarcoma
- Secondary or metastatic tumors
  - Lymphoma
  - Leukemia
  - Histiocytosis
  - Neuroblastoma
  - Wilms tumor

INCREASED SIZE OF VASCULAR SPACE

- Intrahepatic obstruction to hepatic vein outflow
  - Veno-occlusive disease
  - Hepatic vein thrombosis (Budd-Chiari syndrome)
  - Hepatic vein web
  - Suprahepatic
  - Congestive heart failure
  - Pericardial disease
  - Tamponade
  - Constrictive pericarditis
  - Hematopoietic: sickle cell anemia, thalassemia

INCREASED SIZE OF BILIARY SPACE

- Congenital hepatic fibrosis

INCREASED SIZE OF BILIARY SPACE

Congenital hepatic fibrosis

Caroli disease

Extrahepatic obstruction

IDIOPATHIC (? "BENIGN")

(2) the span of dullness to percussion; or (3) the length of the vertical axis of the liver, as estimated from imaging techniques. In children, the normal liver edge can be felt up to 2?cm below the right costal margin. In a newborn infant, extension of the liver edge more than 3.5?cm below the costal margin in the right midclavicular line suggests hepatic enlargement. Measurement of *liver span* is carried out by percussing the upper margin of dullness and by palpating the lower edge in the right midclavicular line; it may be more reliable than an extension of the liver edge alone; the two measurements may correlate poorly.

The liver span increases linearly with body weight and age in both sexes, ranging from about 4.5–5?cm at 1 wk of age to approximately 7–8?cm in boys and 6–6.5?cm in girls by 12 yr of age. The lower edge of the right lobe of the liver extends downward **(Riedel lobe)** and may be palpable as a broad mass in some normal people. An enlarged left lobe of the liver may be palpable in the epigastrium of some patients with cirrhosis. Downward displacement of the liver by the diaphragm or thoracic organs can create an erroneous impression of hepatomegaly.

Examination of the liver should note the consistency, contour, tenderness, or the presence of any masses or bruits, as well as assessment of spleen size. Documentation of the presence of ascites and any stigmata of chronic liver disease is important.

Ultrasonography is useful in assessment of **liver size and consistency**, as well as **gallbladder size**. Hyperechogenic hepatic parenchyma can be seen with metabolic disease (glycogen storage disease) or fatty liver (from obesity, malnutrition, hyperalimentation, corticosteroids). Gallbladder distention may be seen in infants with sepsis. The gallbladder is often absent in infants with biliary atresia. Gallbladder length normally varies from 1.5 to 5.5?cm (average, 3.0) in infants to 4 to 8?cm in adolescents; width ranges from 0.5 to 2.5?cm for all ages.

JAUNDICE (ICTERUS).

Yellow discoloration of the sclera, skin, and mucous membranes is a sign that hyperbilirubinemia exists (Chapter 91.3). Clinically apparent jaundice in children and adults occurs when the serum concentration of bilirubin reaches 2–3?mg/dL (34–51?µmol/L); however, the neonate may not appear icteric until the bilirubin level is over 5?mg/dL (85?µmol/L). Jaundice may be the earliest and only sign of hepatic dysfunction. Liver disease must be suspected in the infant who may appear only mildly jaundiced, but has dark urine or acholic (light-colored) stools. Immediate evaluation to establish the cause is required.

Measurement of the total serum bilirubin concentration allows quantitation of jaundice. Bilirubin occurs in plasma in four forms: (1) *unconjugated bilirubin* tightly bound to albumin; (2) *free* or *unbound bilirubin* (the form responsible for kernicterus, because it can cross cell membranes); (3) *conjugated bilirubin* (the only fraction to appear in urine); and (4) *delta* (d) *fraction* (bilirubin covalently bound to albumin), which appears in serum when hepatic excretion of conjugated bilirubin is impaired in patients with hepatobiliary disease. The d fraction permits conjugated bilirubin to persist in the circulation and delays resolution of jaundice. Although the terms *direct* and *indirect* bilirubin are used equivalently with *conjugated* and *unconjugated* bilirubin, this is not quantitatively correct, because the direct fraction includes both conjugated bilirubin and d bilirubin. An elevation of serum bile acids is frequently seen in the presence of any form of cholestasis.

Investigation of jaundice in an infant or older child must include determination of the accumulation of either unconjugated or conjugated bilirubin. An unconjugated hyperbilirubinemia may indicate increased production, hemolysis, reduced hepatic removal, or altered metabolism of bilirubin (Box 336–2). A conjugated bilirubinemia (>20% of total) reflects

BREAST MILK JAUNDICE

decreased excretion by damaged hepatic parenchymal cells or disease of biliary tract, which may be due to sepsis, endocrine or metabolic disease, inflammation of the liver, or obstruction (Box 336–3).

PRURITUS.

Intense generalized itching may occur in patients with cholestasis (conjugated hyperbilirubinemia). Pruritus is unrelated to the degree of hyperbilirubinemia; deeply jaundiced patients may be asymptomatic, and vice versa. Although retained components of bile are important, the cause is probably multifactorial as evidenced by the symptomatic relief of pruritus following administration of various therapeutic agents including bile acid–binding agents such as cholestyramine; choleretic agents such as phenobarbital or ursodeoxycholic acid; opiate antagonists; antihistamines; and antibiotics such as rifampin. Surgical diversion of bile via a procedure called partial external biliary diversion has provided relief for medically refractory pruritus.

SPIDER ANGIOMAS.

Vascular spiders (telangiectasias), characterized by central pulsating arterioles from which small, wiry venules radiate, may be seen in patients with chronic liver disease, usually most prominent in the face and chest. These are presumably reflective of altered estrogen metabolism in the presence of hepatic dysfunction.

PALMAR ERYTHEMA.

Blotchy erythema, most noticeable over the thenar and hypothenar eminences and on the tips of the fingers, is also noted in patients with chronic liver disease. These may be due to vasodilation and increased blood flow.

XANTHOMAS.

The marked elevation of serum cholesterol (to levels > 500?mg/dL) associated with chronic cholestasis may cause the deposition of lipid in the dermis and subcutaneous tissue. Brown nodules may develop first over the extensor surfaces of the extremities; rarely, xanthelasma of the eyelids develops.

PORTAL HYPERTENSION.

The portal vein drains the splanchnic area (abdominal portion of the gastrointestinal tract, pancreas, and spleen) into the hepatic sinusoids. Normal portal pressure gradient, the pressure difference between the portal vein and the systemic veins (hepatic veins or inferior vena cava), is 3–6?mm?Hg, with “clinically significant portal hypertension” being a threshold above 10?mm?Hg. Portal hypertension is the main complication of cirrhosis, directly responsible for two of its most common and potentially lethal complications—ascites and variceal hemorrhage.

ASCITES.

Ascites may be associated with urinary tract abnormalities, metabolic diseases (such as lysosomal storage diseases), congenital or acquired heart disease, and hydrops fetalis. Factors favoring the intra-abdominal accumulation of fluid include (1) decreased plasma colloid osmotic pressure; (2) increased capillary hydrostatic pressure; (3) increased ascitic colloid osmotic fluid pressure; and (4) decreased ascitic fluid hydrostatic pressure. Abnormal renal sodium retention must be considered (Chapter 351). The onset of ascites in the child with chronic liver disease means that the two prerequisite conditions for ascites are present—portal hypertension and hepatic insufficiency.

VARICEAL HEMORRHAGE.

Gastroesophageal varices are the more clinically significant portosystemic collaterals because of their propensity to rupture and cause life-threatening hemorrhage. Variceal hemorrhage results from increased pressure within the varix, which leads to changes in the diameter of the varix and increased wall tension. When the variceal wall strength is exceeded, physical rupture of the varix results, and given the high blood flow and pressure in the portosystemic collateral system coupled with the lack of a natural mechanism to tamponade variceal bleeding, the rate of hemorrhage can be striking.

ENCEPHALOPATHY.

Hepatic encephalopathy can involve any neurologic function, and may be prominent, or it may present in subtle forms such as deterioration of school performance, depression, or emotional outbursts. It may be recurrent and precipitated by intercurrent illness, drugs, bleeding, or electrolyte

Myeloproliferative disease (21-trisomy)

and acid-base disturbances. The appearance of hepatic encephalopathy depends on the presence of portosystemic shunting, alterations in the blood-brain barrier, and the interactions of toxic metabolites with the central nervous system. Postulated causes include altered ammonium metabolism, synergistic neurotoxins, or “false neurotransmitters” with plasma amino acid imbalance (Chapter 345).

ENDOCRINE ABNORMALITIES.

Endocrine abnormalities are more common in adults with hepatic disease than in children. They reflect alterations in hepatic synthetic, storage, and metabolic functions, including those concerned with hormonal metabolism in the liver. Proteins that bind hormones in plasma are synthesized in the liver, and steroid hormones are conjugated in the liver and excreted in the urine; failure of such functions may have clinical consequences. Endocrine abnormalities may also result from malnutrition or specific deficiencies.

RENAL DYSFUNCTION.

There is a close relationship between hepatic and renal dysfunction. Systemic disease or toxins may affect both organs simultaneously, or parenchymal liver disease may produce secondary impairment of renal function, and vice versa. In hepatobiliary disorders, there may be renal alterations in sodium and water economy, impaired renal concentrating ability, and alterations in potassium metabolism. Ascites in patients with cirrhosis may be related to inappropriate retention of sodium by the kidneys, with expansion of plasma volume, or to sodium retention mediated by diminished effective plasma volume. *Hepatorenal syndrome* is defined as functional renal failure in patients with end-stage liver disease. The pathophysiology is poorly defined but the hallmark is intense renal vasoconstriction (mediated by hemodynamic, humoral, or neurogenic mechanisms) with coexistent systemic vasodilation. The diagnosis is supported by the findings of oliguria (<1?mL/kg/day); a characteristic pattern of urine electrolyte abnormalities (urine sodium of <10?mEq/L, fractional excretion of sodium of <1%, urine:plasma creatinine ratio < 10 and normal urinary sediment), absence of hypovolemia and exclusion of other kidney pathology. The best treatment is timely liver transplantation, as complete renal recovery can be expected.

PULMONARY INVOLVEMENT.

Hepatopulmonary syndrome is characterized by the typical triad of hypoxemia, intrapulmonary vascular dilations, and liver disease. In this entity, there is intrapulmonic right-to-left shunting of blood, which results in systemic desaturation. It should be suspected and investigated in the child with chronic liver disease with history of shortness of breath or exercise intolerance and clinical examination findings of cyanosis (particularly of the lips and fingers), digital clubbing, and oxygen saturations below 96%, particularly in the upright position. Treatment is timely liver transplantation; successful pulmonary resolution follows.

RECURRENT CHOLANGITIS.

Ascending infection of the biliary system is most often seen in pediatric cholestatic liver disease, due most commonly to gram-negative enteric organisms, such as *E. coli, Klebsiella, Pseudomonas*, and *Enterococcus*. Liver transplantation is the definitive effective treatment for recurrent cholangitis in the child with chronic cholestatic liver disease, especially when medical therapy is not effective.

Miscellaneous Manifestations of Liver Dysfunction.

Nonspecific signs of acute and chronic liver disease include (1) *anorexia*, which often affects patients with anicteric hepatitis and with cirrhosis associated with chronic cholestasis; (2) *abdominal pain or distention* resulting from ascites, spontaneous peritonitis, or visceromegaly; (3) *malnutrition and growth failure;* and (4) *bleeding*, which may be due to altered synthesis of coagulation factors (biliary obstruction with vitamin K deficiency or excessive hepatic damage) or to portal hypertension with hypersplenism. In the presence of hypersplenism, there may be decreased synthesis of specific clotting factors, production of qualitatively abnormal proteins, or alterations in platelet number and function. Altered drug metabolism may prolong the biologic half-life of commonly administered medications.

336.1 Evaluation of Patients with Possible Liver Dysfunction

Adequate evaluation of an infant, child, or adolescent with suspected liver disease involves an appropriate and accurate history, a carefully performed physical examination, and skillful interpretation of signs and symptoms. Further evaluation is aided by judicious selection of diagnostic tests, followed by a liver biopsy or the use of imaging modalities. Most of the so-called liver function tests do not measure specific hepatic functions; a rise in serum aminotransferase (transaminase) level reflects liver cell injury; an increase in immunoglobulin level reflects an immunologic response to injury; or an elevation in serum bilirubin level may reflect any of several disturbances of bilirubin metabolism outlined in Boxes 336–2 and 336–3 . Any single biochemical assay provides limited information, which must be placed in the context of the entire clinical and historic picture. The most cost-efficient approach is to become familiar with the rationale, implications, and limitations of a selected group of tests so that specific questions can be answered.

For a patient with suspected liver disease, evaluation addresses the following issues in sequence: (1) Is liver disease present? (2) If so, what is its nature? (3) What is its severity? (4) Is specific treatment available? (5) How can we monitor the response to treatment? and (6) What is the prognosis?

Biochemical Tests.

Laboratory tests commonly used to screen for or to confirm a suspicion of liver disease include measurements of serum transaminase, bilirubin (total and fractionated) and alkaline phosphatase (AP) levels, as well as determinations of prothrombin time (PT) or international normalized ratio (INR) and albumin level. These tests are complementary and provide an estimation of synthetic and excretory functions and may suggest the nature of the disturbance (e.g., inflammation or cholestasis).

Acute liver cell injury (parenchymal disease) in viral hepatitis, drug- or toxin-induced liver disease, shock, hypoxemia, or metabolic disease is best reflected by marked increases in serum aminotransferase levels. Cholestasis (obstructive disease) involves regurgitation of bile components into serum; the serum levels of total and conjugated bilirubin and serum bile acids are elevated. Elevations in serum alkaline phosphatase, 5' nucleotidase (5' NT), and ?-glutamyl transpeptidase (GGT) levels are also sensitive indicators of obstruction or inflammation of the biliary tract.

The severity of the liver disease may be reflected in (1) *clinical signs* (occurrence of encephalopathy, variceal hemorrhage, worsening jaundice, apparent shrinkage of liver mass owing to massive necrosis, or onset of ascites) or in (2) *biochemical alterations* (hypoglycemia, hyperammonemia, electrolyte imbalance, continued hyperbilirubinemia, marked hypoalbuminemia, or prolonged PT or INR unresponsive to parenteral administration of vitamin K).

Fractionation of the total serum bilirubin level into *conjugated and unconjugated bilirubin fractions* helps to distinguish between elevations caused by hemolysis and those caused by hepatic dysfunction. A predominant elevation in the conjugated bilirubin level provides a relatively sensitive index of hepatocellular disease and hepatic excretory dysfunction, whereas elevation in transaminase levels are more highly sensitive indices of hepatocellular damage.

Alanine aminotransferase (ALT, serum glutamate pyruvate transaminase) is liver specific, whereas *aspartate aminotransferase* (AST, serum glutamic-oxaloacetic transaminase) is derived from other organs in addition to the liver. The most marked rises of both AST and ALT levels may occur with acute hepatocellular injury—a several thousand-fold elevation may result from acute viral hepatitis, toxic injury, hypoxia or hypoperfusion. After blunt abdominal trauma, parallel elevations in transaminase levels may provide an early clue to hepatic injury. A differential rise or fall in AST and ALT levels can sometimes provide useful information. In acute hepatitis, the rise in ALT may be greater than the rise in AST. In alcohol-induced liver injury, fulminant echovirus infection, and various metabolic diseases, more predominant rises in AST have been reported. In chronic liver disease or in intrahepatic and extrahepatic biliary obstruction, AST and ALT elevations may be less marked. *Nonalcoholic steatohepatitis (NASH),* also known as nonalcoholic fatty

liver disease, is a chronic liver disorder that is seen in obese children presenting with elevated serum transaminase levels. Its notable characteristic is the similar histology to alcoholic-induced liver injury in the absence of alcohol abuse.

Hepatic synthetic function is reflected in *serum albumin* and *protein* levels and in the *PT* or *INR.* Examination of *serum globulin* concentration and of the relative amounts of the globulin fractions may be helpful. Gamma-globulin levels are often high, and increased titers of smooth muscle antibody as well as antinuclear antibodies, anti–liver-kidney-microsome (LKM) antibody, and antimitochondrial antibodies may be found in patients with autoimmune hepatitis. A resurgence in *a-fetoprotein* levels may suggest hepatoma or hereditary tyrosinemia. Hypoalbuminemia caused by depressed synthesis may complicate severe liver disease and serve as a prognostic factor. Deficiencies of *factor V* and of the *vitamin K–dependent factors* (*II, VII, IX,* and *X*) may occur in patients with severe liver disease or fulminant hepatic failure. If the PT or INR is prolonged as a result of intestinal malabsorption of vitamin K (resulting from cholestasis) or decreased nutritional intake of vitamin K, then parenteral administration of vitamin K should correct the coagulopathy, leading to normalization within 24?hr. Unresponsiveness to vitamin K would suggest hepatic disease. Persistently low levels of factor VII are evidence of a poor prognosis in fulminant liver disease.

Interpretation of results of biochemical tests of hepatic structure and function must be made in the context of age-related changes. The activity of *alkaline phosphatase (AP)* varies considerably with age. Normal growing children have significant elevations of serum AP activity originating from influx into serum of the isoenzyme that originates in bone, particularly in rapidly growing adolescents. Therefore, an isolated increase in AP does not indicate hepatic or biliary disease if other liver function test results are normal. Other enzymes such as *5' NT and GGT* are increased in cholestatic conditions, and may be more specific for hepatobiliary disease. 5' NT is located in both sinusoidal and canalicular membranes, and is not found in bone. GGT exhibits high enzyme activity in early life that declines rapidly with age. Cholesterol concentrations increase throughout life. *Cholesterol levels* may is markedly elevated in patients with cholestasis, whether the cause is intrahepatic or extrahepatic. On the other hand, with acute liver disease, such as hepatitis, serum cholesterol levels may be depressed.

Interpretation of *serum ammonia* values must be carried out with caution because of variability in their physiologic determinants and the inherent difficulty in laboratory measurement.

Liver Biopsy.

Liver biopsy combined with clinical data can suggest a cause in most cases. Specimens of liver tissue can be used (1) to provide a precise histology diagnosis in patients with neonatal cholestasis, chronic active hepatitis, metabolic liver disease, suspected Reye syndrome, intrahepatic cholestasis (paucity of bile ducts), congenital hepatic fibrosis, or undefined portal hypertension; (2) for enzyme analysis to detect inborn errors of metabolism; and (3) for analysis of stored material such as iron, copper, or specific metabolites. Liver biopsies can monitor responses to therapy or detect complications of treatment with potentially hepatotoxic agents, including but not exclusively, aspirin, anti-infectives (erythromycin, minocycline, ketoconazole, isoniazid), antimetabolites, anti-neoplastics, or anticonvulsant agents.

In infants and children, needle biopsy of the liver is easily accomplished through the percutaneous approach. The amount of tissue obtained, even in small infants, is usually sufficient for histologic interpretation and for biochemical analyses, if the latter are deemed necessary. Percutaneous liver biopsy can be performed safely in infants as young as 1 wk. Patients usually require only sedation and *local* anesthesia. Contraindications include prolonged PT or INR; thrombocytopenia; suspicion of a vascular, cystic, or infectious lesion in the path of the needle; and severe ascites. Therefore, if administration of fresh frozen plasma or of platelet transfusions fails to correct a prolonged PT, INR, or thrombocytopenia, a tissue specimen may be obtained via alternative techniques. Considerations include either the open laparotomy (wedge) approach by a general surgeon, or the transjugular approach under ultrasound and fluoroscopic guidance by an experienced pediatric interventional radiologist in an appropriately equipped fluoroscopy suite. The risk of development of a complication such as hemorrhage, hematoma, creation of an arteriovenous fistula, pneumothorax, or bile peritonitis is very small.

Hepatic Imaging Procedures.

Various techniques help define the size, shape, and architecture of the liver and the anatomy of the intrahepatic and extrahepatic biliary trees. Although imaging may not provide a precise histologic and biochemical diagnosis, specific questions can be answered, such as whether hepatomegaly is related to accumulation of fat or glycogen or is due to a tumor or cyst. These studies may direct further evaluation such as percutaneous biopsy and make possible prompt referral of patients with biliary obstruction to a surgeon. Choice of imaging procedure should be part of a carefully formulated diagnostic approach, with avoidance of redundant demonstrations by several techniques.

A *plain roentgenographic study* may suggest hepatomegaly, but a carefully performed physical examination gives a more reliable assessment of liver size. The liver may appear less dense than normal in patients with fatty infiltration or more dense with deposition of heavy metals such as iron. A hepatic or biliary tract mass may displace an air-filled loop of bowel. Calcifications may be evident in the liver (parasitic and neoplastic disease), in the vasculature (with portal vein thrombosis), or in the gallbladder or biliary tree (gallstones). Collections of gas may be seen within the liver (abscess), biliary tract, or portal circulation (necrotizing enterocolitis).

Ultrasonography (US) provides information about the size, composition, and blood flow of the liver. Increased echogenicity is observed with fatty infiltration, and mass lesions as small as 1–2?cm may be shown. US has replaced cholangiography in detecting stones in the gallbladder or biliary tree. Even in neonates, US can assess gallbladder size, detect dilatation of the biliary tract, and define a choledochal cyst. In infants with biliary atresia, US findings may include small or absent gallbladder; nonvisualization of the common duct; and presence of the “triangular cord sign,” a triangular/tubular-shaped echogenic density in the bifurcation of the portal vein, representing fibrous remnants at the porta hepatis. In patients with portal hypertension, Doppler US can evaluate patency of the portal vein, demonstrate

collateral circulation, and assess size of spleen and amount of ascites. Relatively small amounts of ascitic fluid can also be detected. The use of Doppler US has been helpful in determining vascular patency after orthotopic liver transplantation.

Computed tomography (CT) scanning provides information similar to that obtained by US but is less suitable for use in patients younger than 2 yr of age because of the small size of structures, the paucity of intra-abdominal fat for contrast, and the need for heavy sedation or general anesthesia. *Magnetic resonance imaging (MRI)* is a useful alternative. Magnetic resonance cholangiography can be of value in differentiating biliary tract lesions. CT scan or MRI may be more accurate than US in detecting focal lesions such as tumors, cysts, and abscesses. When enhanced by contrast medium, CT scanning may reveal a neoplastic mass density only slightly different from that of a normal liver. When a hepatic tumor is suspected, CT scanning is the best method to define anatomic extent, solid or cystic nature, and vascularity. CT scanning can also reveal subtle differences in density of liver parenchyma, the average liver attenuation coefficient being reduced with fatty infiltration. Increases in density may occur with diffuse iron deposition or with glycogen storage. In differentiating obstructive from nonobstructive cholestasis, CT scanning or MRI identifies the precise level of obstruction more frequently than US. Either CT scanning or US may be used to guide percutaneously placed fine needles for biopsies, aspiration of specific lesions, or cholangiography.

Radionuclide scanning relies on selective uptake of a radiopharmaceutical agent. Commonly used agents include (1) technetium 99m-labeled sulfur colloid, which undergoes phagocytosis by Kupffer cells; (2) ^{99m}Tc-iminodiacetic acid agents, which are taken up by hepatocytes and excreted into bile in a fashion similar to bilirubin; and (3) gallium 67, which is concentrated in inflammatory and neoplastic cells. The anatomic resolution possible with hepatic scintiscans is generally less than that obtained with CT scanning, MRI, or US.

The ^{99m}Tc-sulfur colloid scan may detect focal lesions (tumors, cysts, or abscesses) greater than 2–3?cm in diameter. This modality may help to evaluate patients with possible cirrhosis and with patchy hepatic uptake and a shift of colloid uptake from liver to bone marrow.

The ^{99m}Tc-substituted iminodiacetic acid dyes may differentiate intrahepatic cholestasis from extrahepatic obstruction in neonates. Imaging results are best when scanning is preceded by a 5–7-day period of treatment with phenobarbital to stimulate bile flow. After intravenous injection, the isotope is normally detected in the bowel within 1–2?hr. In the presence of extrahepatic obstruction, excretion of the isotope is delayed; accordingly, serial scans should be made for up to 24?hr after injection. Early in the course of biliary atresia, hepatocyte function is usually good; uptake (clearance) occurs rapidly, but excretion into the intestine is absent. In contrast, uptake is poor in parenchymal liver disease, such as neonatal hepatitis, but excretion into the bile and intestine eventually ensues.

Cholangiography, direct visualization of the intrahepatic and extrahepatic biliary tree after injection of opaque material, may be required in some patients to evaluate the cause, location, or extent of biliary obstruction. Percutaneous transhepatic cholangiography with a fine needle is the technique of choice in infants and young children. The likelihood of opacifying the biliary tract is excellent in patients in whom CT scanning, MRI, or ultrasonography has shown dilated ducts. Percutaneous transhepatic cholangiography has been used to outline the biliary ductal system.

Endoscopic retrograde cholangiopancreatography (ERCP) is an alternative method of examining the bile ducts in older children. The papilla of Vater is cannulated under direct vision

---

through a fiberoptic endoscope, and contrast material is injected into the biliary and pancreatic ducts to outline the anatomy.

Selective angiography of the celiac, superior mesenteric, or hepatic artery may be used to visualize the hepatic or portal circulation. Both arterial and venous circulatory systems of the liver can be examined. Angiography is frequently required to define the blood supply of tumors before surgery and is useful in the study of patients with known or presumed portal hypertension. The patency of the portal system, the extent of collateral circulation, and the caliber of vessels under consideration for a shunting procedure can be evaluated. MRI can provide similar information.

Chapter 337 - Cholestasis

Hassan H. A-Kader
William F. Balistreri

337.1 Neonatal Cholestasis

Neonatal cholestasis is defined as prolonged elevation of serum levels of conjugated bilirubin beyond the first 14 days of life. Jaundice that appears after 2 wk of age, progresses after this time, or does not resolve at this time should be evaluated and a direct bilirubin level determined. Cholestasis in a newborn may be due to infectious, genetic, metabolic, or undefined abnormalities giving rise either to mechanical obstruction of bile flow or to functional impairment of hepatic excretory function and bile secretion (see Box 336–3). An example of the former is stricture or obstruction of the common bile duct; biliary atresia is the prototypic obstructive abnormality. Functional impairment of bile secretion may result from congenital defects or damage to liver cells or to the biliary secretory apparatus. Neonatal cholestasis may be divided into extrahepatic and intrahepatic disease (Fig. 337–1). The clinical features of any form of cholestasis are similar. In an affected neonate, the diagnosis of certain entities, such as galactosemia, sepsis, and hypothyroidism, is relatively simple. In most cases, however, the cause of cholestasis is more obscure. Differentiation among *biliary atresia*, idiopathic *neonatal hepatitis*, and *intrahepatic cholestasis* is particularly difficult.

MECHANISMS.

The two most likely pathogenetic mechanisms are virus-induced liver injury or metabolic liver disease.

Figure 337.1-1 Neonatal cholestasis. Conceptual approach to the group of diseases presenting as cholestasis in the neonate. There are areas of overlap—patients with extrahepatic biliary atresia may have some degree of intrahepatic injury. Patients with “idiopathic” neonatal hepatitis may in the future be determined to have a primary metabolic or viral disease.

Metabolic liver disease caused by inborn errors of bile acid metabolism is associated with accumulation of toxic primitive bile acids and failure to produce normal choleretic and trophic bile acids. The clinical and histologic manifestations are nonspecific and are similar to those in other forms of neonatal hepatobiliary injury. It

is also possible that autoimmune mechanisms may be responsible for some of the enigmatic forms of neonatal liver injury. Overall, the mechanisms are not well documented. Some of the histologic manifestations of hepatic injury in early life are not common in older individuals. Giant cell transformation of hepatocytes occurs frequently in infants with cholestasis and may occur in any form of neonatal liver injury. It is more frequent and more severe, however, in intrahepatic forms of cholestasis (neonatal hepatitis or intrahepatic bile duct paucity). The clinical and histologic findings thought to exist in patients with neonatal hepatitis and in those with biliary atresia have suggested that these diseases are manifestations of a single basic process, with an undefined initiating insult causing inflammation of the liver cells or of the cells within the biliary tract. If bile duct epithelium is the predominant site of disease, cholangitis may result and lead to progressive sclerosis and narrowing of the biliary tree, the ultimate state being complete obliteration *(biliary atresia)*. Injury to liver cells may present the clinical and histologic picture of *neonatal hepatitis*. This concept does not account for all phenomena but offers an explanation for well-documented cases of unexpected postnatal evolution of these disease processes; infants initially regarded as having neonatal hepatitis, with a patent biliary system shown on cholangiography, have later been found to have biliary atresia.

Functional abnormalities in the generation of bile flow may also have a role in neonatal cholestasis. Bile flow is directly dependent on effective hepatic bile acid excretion. During the phase of relatively inefficient liver cell transport and metabolism of bile acids in early life, minor degrees of hepatic injury may further decrease bile flow and lead to production of abnormal toxic bile acids. Selective impairment of a single step in the series of events involved in hepatic excretion may produce the full expression of a cholestatic syndrome. A small number of

cholestatic syndromes have a familial pattern. Byler disease (progressive familial intrahepatic cholestasis [PFIC]) and benign recurrent cholestasis are presumably related to impaired membrane transport of bile acids. Specific defects in bile acid synthesis have been found in infants with intrahepatic cholestasis and in infants with Zellweger syndrome. Severe forms of familial cholestasis have been associated with neonatal hemochromatosis and an aberration in the contractile proteins that compose the cytoskeleton of the hepatocyte. Sepsis is known to cause cholestasis, presumably mediated by an endotoxin produced by *Escherichia coli*.

EVALUATION.

The evaluation of the infant with jaundice should follow a logical, cost-effective sequence in a multistep process (Table 337–1). Although cholestasis in the neonate may be the initial manifestation of numerous disorders, the clinical manifestations are usually similar and provide very few clues about etiology. Affected infants have icterus, dark urine, light or acholic stools, and hepatomegaly, all resulting from decreased bile flow due to either hepatocyte injury or bile duct obstruction. Hepatic synthetic dysfunction may lead to hypoprothrombinemia and a bleeding disorder. Therefore, administration of vitamin K should be the initial treatment of cholestatic infants to prevent hemorrhage.

In contrast to unconjugated hyperbilirubinemia, which may be physiologic, cholestasis in the neonate is always pathologic and prompt differentiation is imperative. The initial step in identification of cholestasis is the finding that more than 20% of the hyperbilirubinemia is conjugated bilirubin. The next step is to recognize conditions that cause cholestasis and for which specific therapy is available to prevent further damage and avoid long-term complications such as *sepsis*, an *endocrinopathy* (hypothyroidism or panhypopituitarism), *nutritional hepatotoxicity* caused by a specific metabolic illness (galactosemia), or other *metabolic diseases* (tyrosinemia).

Hepatobiliary disease may be the initial manifestation of homozygous a_1 -antitrypsin deficiency or of cystic fibrosis. Neonatal liver disease may also be associated with congenital syphilis and specific viral infections notably echo virus and herpesviruses including cytomegalovirus (CMV). The hepatitis viruses (A, B, C) rarely cause neonatal cholestasis.

The final step in evaluating neonates with cholestasis is to differentiate extrahepatic biliary atresia from neonatal hepatitis.

Neonatal Hepatitis Syndrome (Intrahepatic Cholestasis).

The term *neonatal hepatitis* implies intrahepatic cholestasis (see Fig. 337–1), which has various forms:

Idiopathic neonatal hepatitis, which can occur in either a sporadic or a familial form, is a disease of unknown cause. These patients presumably are afflicted with a specific yet undefined metabolic or viral disease. In the past, patients with a_1 -antitrypsin deficiency were included in this category; after characterization

TABLE 337.1-1 -- **Value of Specific Tests in the Evaluation of Patients with Suspected Neonatal Cholestasis**

Test	Rationale
Serum bilirubin fractionation	Documents cholestasis
Assessment of stool color	Indicates bile flow into intestine
Urine/serum bile acids measurement	Confirms cholestasis; may indicate inborn error of bile acid biosynthesis
Hepatic synthetic function (albumin, coagulation profile)	Indicates severity of hepatic dysfunction
a_1 phenotype	Suggests (or excludes) PiZZ
Thyroxine and TSH	Suggests (or excludes) endocrinopathy
Sweat chloride/mutation analysis	Suggests (or excludes) cystic fibrosis
Urine/serum amino acids and urine reducing substances	Suggests (or excludes) metabolic liver disease

Ultrasonography	Suggests (or excludes) choledochal cyst; may detect the triangular cord (TC) sign suggesting biliary atresia
Hepatobiliary scintigraphy	Documents bile duct patency or obstruction
Liver biopsy	Distinguishes biliary atresia from neonatal hepatitis; suggests alternative diagnosis

Modified from Balistreri WF, Schubert WK: Liver disease in infancy and childhood. In Schiff L, Schiff ER (editors): Diseases of the Liver, 8th ed. Philadelphia, Lippincott, 1999.

of this specific metabolic disease, it is possible to define this subgroup of patients precisely.

Infectious hepatitis in a neonate may be shown to be due to a specific virus, such as herpes simplex, enteroviruses, CMV, or, rarely, hepatitis B. This accounts for a small percentage of cases of neonatal hepatitis syndrome.

Cases of **intrahepatic cholestasis,** a heterogeneous subset of cholestatic diseases due to congenital defects in hepatic excretory function that may present as neonatal cholestasis.

Intrahepatic Bile Duct Paucity.

Some syndromes characterized morphologically by intrahepatic cholestasis may be clinically manifested either as neonatal hepatitis or as cholestasis in an older child. As patients mature, clinical and histologic features may suggest a specific syndrome. Certain cases are associated with bile duct “paucity” (often erroneously called intrahepatic biliary atresia), which designates an absence or marked reduction in the number of interlobular bile ducts in the portal triads, with normal-sized branches of portal vein and hepatic arteriole. This unusual histologic feature may represent either congenital bile duct absence, partial failure of bile duct development, progressive bile duct atrophy, or disappearance of the bile ducts due to segmental destructive processes. Biopsy in early life often reveals an inflammatory process involving the bile ducts; subsequent biopsy specimens then show subsidence of the inflammation with residual reduction in the number and diameter of bile ducts, analogous to the “disappearing bile duct syndrome” noted in adults with immune-mediated disorders.

Observations suggest that it is possible to identify distinctive syndromes of isolated intrahepatic bile duct paucity and an intact extrahepatic biliary tree.

Alagille syndrome (arteriohepatic dysplasia) is the most common syndrome incorporating intrahepatic bile duct paucity. Serial assessment of hepatic histology often suggests progressive destruction of bile ducts. Clinical manifestations of Alagille syndrome are expressed in various degrees and may be nonspecific; they include unusual *facial characteristics* (broad forehead; deep-set, widely spaced eyes; long, straight nose; and an underdeveloped mandible). There may also be *ocular* abnormalities (posterior embryotoxon), *cardiovascular* abnormalities (usually peripheral pulmonic stenosis, sometimes tetralogy of Fallot), *vertebral* arch defects and failure of anterior vertebral arch fusion (butterfly vertebrae), and tubulointerstitial *nephropathy*. Other findings such as growth retardation and defective spermatogenesis may reflect nutritional deficiency. The prognosis for prolonged survival is good, but patients are likely to have pruritus, xanthomas with markedly elevated serum cholesterol levels, and neurologic complications of vitamin E deficiency if untreated. Mutations in human Jagged 1 gene *(JAG1)*, which encodes a ligand for the notch receptor, are linked to Alagille syndrome.

There are several forms of intrahepatic cholestasis due to defects in specific transport proteins involved in bile formation (Table 337–2). **Byler disease,** a severe form of *progressive intrahepatic cholestasis* (PFIC type 1), was initially described in the Amish kindred of Jacob Byler. The disease is characterized by unique structural abnormalities in the bile canalicular membrane. Affected patients present with failure to thrive, steatorrhea, pruritus, rickets, and low ?-glutamyl transpeptidase levels. Cirrhosis gradually develops. The major clinical differentiation from Alagille syndrome is the absence of bile duct paucity and extrahepatic features.

PFIC type 1 (Byler disease) is mapped to chromosome 18q12. Affected patients have low serum levels of ?-glutamyltransferase, normal serum cholesterol, and high serum bile acid levels. A mutation in P-type membrane adenosine triphosphatase is the responsible mechanism in Amish families.

PFIC type 2 is similar to Byler disease but is present in non-Amish families (Middle Eastern Europeans) and has a gene locus at chromosome 2q24. Mutations of BSEP gene, which codes for a bile canalicular adenosine triphosphate-dependent bile acid transporter, may be responsible.

PFIC type 3 is characterized by high serum levels of a-glutamyltransferase and histologically by portal bile duct inflammation and proliferation. There is complete absence of the multidrug resistance 3 P glycoprotein, with deficient translocation of phosphatidylcholine across the canalicular membrane. Mothers who are heterozygous for this gene are at risk for intrahepatic cholestasis of pregnancy.

Aagenaes syndrome is a form of idiopathic familial intrahepatic cholestasis associated with lymphedema of the lower extremities. The relation between the liver disease and lymphedema is not understood and may be attributable to decreased hepatic lymph flow or hepatic lymphatic hypoplasia. Affected patients usually present with episodic cholestasis with elevation of serum aminotransferases, alkaline phosphatase, and bile acids. Between the episodes the patients are usually asymptomatic and the biochemical indices improve. The locus for Aagenaes syndrome has been mapped to a 6.6-cM interval on chromosome 15q.

TABLE 337.1-2 -- **Genetic Forms of Intrahepatic Cholestasis or Hyperbilirubinaemia**

Disease	Chromosome	Gene	Defect	Phenotype

PFIC type 1	18q21	*FIC1*, P type ATPase with homology to a putative aminophospholipid translocator	Pathogenetic mechanism unknown	First recurrent, later permanent and progressive cholestasis, no bile duct proliferation, normal gamma-GT, extrahepatic manifestations in some patients
BRIC	18q21	*FIC1*	Unknown but most likely a regulatory defect of bile salt secretion	Recurrent attacks of severe cholestasis, pruritus, jaundice, steatorrhea, and weight loss. Normal liver function in intervals between the attacks
PFIC type 2	2q24	*BSEP*, bile salt export pump	Deficient canalicular bile salt transport	Progressive cholestasis, no bile duct proliferation, giant cell transformation, lobular and portal fibrosis, normal gamma-GT
PFIC type 3	7q21	*PGY3*	Deficient canalicular phosphatidylcholine transport	Cholestasis, jaundice less prominent, extensive bile duct proliferation and periportal fibrosis, elevated gamma-GT
ICP	e.g., 7q21 heterozygosity	e.g., *PGY3*	May be associated with, e.g., PFIC type 3 but is also associated with other PFIC types	Cholestasis in third trimester of pregnancy, therapeutic effect of ursodeoxycholic acid, associated with increased fetal loss and prematurity
Bile acid synthesis defects	e.g., 8q2.3	e.g., *CYP7B1*	Bile acid synthesis enzyme defects with accumulation of toxic intermediates and deficiency of normal bile acids	Cholestasis since birth, failure to thrive, low to normal gamma-GT
Dubin-Johnson syndrome	10q24	*MRP2/cMOAT,* canalicular multispecific organic anion transporter	Deficient canalicular organic anion transport, including that of bilirubin conjugates	Conjugated hyperbilirubinaemia, increased urinary coproporphyrin isomer I, hepatic lysosomal pigment, normal life span

PFIC = progressive familial intrahepatic cholestasis; BRIC = benign recurrent intrahepatic cholestasis; ICP = intrahepatic cholestasis of pregnancy; PGY = P-glycoprotein; CYP = cytochrome P-450; gamma-GT = gamma-glutamyltransferase.

Not mentioned in the table is Aagenaes syndrome (intrahepatic cholestasis with lymphedema) because the gene defect underlying this disease is unknown.

From Jansen PLM, Muller M:The molecular genetics of familial intrahepatic cholestasis. Gut 2000; 47: 1–5.

Zellweger (cerebrohepatorenal) syndrome is a rare autosomal recessive genetic disorder marked by progressive degeneration of the liver and kidneys (Chapter 75.2). The incidence is estimated to be 1/100,000 births; the disease is usually fatal within 6–12 mo. Affected infants have severe, generalized hypotonia and markedly impaired neurologic function with psychomotor retardation. Patients have an abnormal head shape and unusual facies, hepatomegaly, renal cortical cysts, stippled calcifications of the patellas and greater trochanter, and ocular abnormalities. Hepatic cells on ultrastructural examination show an absence of peroxisomes.

Neonatal iron storage disease (NISD) is a rapidly progressive disease characterized by increased iron deposition in the liver, heart, and endocrine organs without increased iron stores in the reticuloendothelial system. Patients have multiorgan failure and shortened survival. Familial cases have been reported and the disease is most likely transmitted in an autosomal recessive or codominant pattern. Laboratory findings include hypoglycemia, hyperbilirubinemia, hypoalbuminemia and profound hypoprothrombinemia. Serum aminotransferases may be high initially but normalize with the progression of the disease. The diagnosis is usually confirmed by buccal mucosal biopsy or magnetic resonance imaging demonstrating extrahepatic siderosis. The prognosis is poor; liver transplantation can be curative. Despite initially encouraging reports, the use of a combination of antioxidants and prostaglandin infusion with chelation may not uniformly improve outcome in the patients with NISD.

Defective bile acid biosynthesis has been postulated to be an initiating or perpetuating factor in neonatal cholestatic disorders; the hypothesis is that inborn errors in bile acid biosynthesis lead to absence of normal trophic or choleretic primary bile acids and accumulation of primitive (hepatotoxic) metabolites. **Inborn errors of bile acid biosynthesis** is a recognizable cause of acute and chronic liver disease; early recognition allows institution of targeted bile acid replacement, which reverses the hepatic injury. Several specific defects have been described:

Deficiency of ?^{4} -3-oxosteroid-5ß reductase, the fourth step in the pathway of cholesterol degradation to the primary bile acids is manifested as significant

developing shortly after birth with coagulopathy and metabolic liver injury resembling tyrosinemia. Hepatic histology is characterized by lobular disarray with giant cells, pseudoacinar transformation, and canalicular bile stasis. Mass spectrometry is required to document increased urinary bile acid excretion and the predominance of oxo-hydroxy and oxo-dihydroxy cholenoic acids. Treatment with cholic acid and ursodeoxycholic acid is associated with normalization of biochemical, histologic, and clinical features.

Deficiency of **3ß-hydroxy C_{27} -steroid dehydrogenase (3-HSD) isomerase,** the second step in bile acid biosynthesis, causes **progressive familial intrahepatic cholestasis**. Affected patients usually have jaundice with increased aminotransferase levels and hepatomegaly; ?-glutamyl transpeptidase levels and serum cholylglycine levels are normal. The histology is variable, ranging from giant cell hepatitis to chronic hepatitis. The diagnosis, suggested by mass spectrometry detection of C^{24} bile acids in urine, which retain the 3ß-hydroxy-$?^5$ structure, can be confirmed by determination of 3-HSD activity in cultured fibroblasts using 7a-hydroxy-$?^5$ cholesterol as a substrate. Primary bile acid therapy, administered orally to downregulate cholesterol 7a-hydroxylase activity, limit the production of 3ß-hydroxy-$?^5$ bile acids, and facilitate hepatic clearance, has been effective in reversing hepatic injury.

Another metabolic defect in bile acid synthesis involves a deficiency in 7a-hydroxylation due to a mutation in the gene for the microsomal **oxysterol 7a-hydroxylase** enzyme, active in the acidic pathway for bile acid synthesis. The defect presents with severe cholestasis, cirrhosis, and liver synthetic failure. Diagnosis is established by fast atom bombardment ionization–mass spectrometry, which reveals elevated urinary excretion of sulfate and glycosulfate conjugates of unsaturated monohydroxy-cholenoic acids, and an absence of primary bile acids. The biochemical findings are consistent with a deficiency in 7a-hydroxylation, leading to the accumulation of hepatotoxic unsaturated monohydroxy bile acids.

BILIARY ATRESIA

The term *biliary atresia* is imprecise because the anatomy of abnormal bile ducts in affected patients varies markedly. A more appropriate terminology would reflect the pathophysiology—namely, *progressive obliterative cholangiopathy*. Patients may have distal segmental bile duct obliteration with patent extrahepatic ducts up to the porta hepatis. This is a surgically correctable lesion, but it is uncommon. However, the most common form of biliary atresia, accounting for approximately 85% of the cases, is obliteration of the entire extrahepatic biliary tree at or above the porta hepatis. This presents a much more difficult problem in surgical management.

Incidence.

Biliary atresia has been detected in 1/10,000–15,000 live births, idiopathic neonatal hepatitis in 1/5,000–10,000. Intrahepatic bile duct paucity appears much less commonly, in about 1/50,000–75,000 live births.

Differentiation of Idiopathic Neonatal Hepatitis from Biliary Atresia.

It may be difficult to clearly differentiate infants with biliary atresia, who require surgical correction, from those with intrahepatic disease (neonatal hepatitis) and patent bile ducts. No single biochemical test or imaging procedure is entirely satisfactory. Diagnostic schemas incorporate clinical, historical, biochemical, and radiologic features.

Idiopathic neonatal hepatitis has a familial incidence of approximately 20%, whereas biliary atresia is unlikely to recur within the same family. A few infants with biliary atresia have an increased incidence of other abnormalities, such as the polysplenia syndrome with abdominal heterotaxia, malrotation, levocardia, and intra-abdominal vascular anomalies. Neonatal hepatitis appears to be more common in premature or small for gestational age infants. Persistently acholic stools suggest biliary obstruction (biliary atresia), but patients with severe idiopathic neonatal hepatitis may have a transient severe impairment of bile excretion. Consistently pigmented stools rule against biliary atresia. The finding of bile-stained fluid on duodenal intubation also excludes biliary atresia. Palpation of the liver may find an abnormal size or consistency in patients with extrahepatic biliary atresia; this is less common with neonatal hepatitis.

Abdominal ultrasound is a helpful diagnostic tool in the evaluation of neonatal cholestasis because it will identify choledocholithiasis, perforation of the bile duct, or other structural abnormalities of the biliary tree such as a choledochal cyst. In patients with biliary atresia, ultrasound may detect associated anomalies such as abdominal polysplenia and vascular malformations. The gallbladder is either not visualized or a micro-gallbladder is seen in patients with biliary atresia. Children with intrahepatic cholestasis caused by idiopathic neonatal hepatitis, cystic fibrosis, or total parenteral nutrition may have similar ultrasonographic findings. Ultrasonographic *triangular cord (TC) sign*, which represents a cone-shaped fibrotic mass cranial to the bifurcation of the portal vein, may be seen in patients with biliary atresia. The echogenic density, which represents the fibrous remnants at the porta hepatis of biliary atresia cases at surgery, may be a helpful diagnostic tool in the evaluation of patients with neonatal cholestasis.

Hepatobiliary scintigraphy with technetium-labeled iminodiacetic acid derivatives is used to differentiate biliary atresia from nonobstructive causes of cholestasis. The hepatic uptake of the agent is normal in patients with biliary atresia but excretion into the intestine is absent. Although the uptake may be impaired in neonatal hepatitis, excretion into the bowel will eventually occur. Obtaining a follow-up scan after 24?hr is of value to determine the patency of the biliary tree. The administration of phenobarbital (5?mg/kg/day) for 5 days before the scan is recommended because it may enhance biliary excretion of the isotope. Hepatobiliary scintigraphy is a sensitive but not specific test for biliary atresia. It fails to identify other structural abnormalities of the biliary tree or vascular anomalies. The lack of the specificity of the test and the need to wait for 5 days makes this procedure less practical and of limited usefulness in the evaluation of children suspected to have biliary atresia.

Percutaneous liver biopsy is a valuable procedure in the evaluation of neonatal

hepatobiliary diseases and provides the most reliable discriminatory evidence. Biliary atresia is characterized by bile ductular proliferation, the presence of bile plugs, and portal or perilobular edema and fibrosis, with the basic hepatic lobular architecture intact. In neonatal hepatitis, there is severe, diffuse hepatocellular disease, with distortion of lobular architecture, marked infiltration with inflammatory cells, and focal hepatocellular necrosis; the bile ductules show little alteration. Giant cell transformation is found in infants with either condition and has no diagnostic specificity.

The histologic changes seen in patients with idiopathic neonatal hepatitis may also occur in various diseases, including a_1 -antitrypsin deficiency, galactosemia, and, various forms of intrahepatic cholestasis. Although paucity of intrahepatic bile ductules may be detected on liver biopsy even within the first few weeks of life, later biopsies in such patients reveal a more characteristic pattern.

Management of Patients with Suspected Biliary Atresia.

All patients suspected of having biliary atresia should undergo exploratory laparotomy and direct cholangiography to determine the presence and site of obstruction. Direct drainage can be accomplished in patients with correctable lesion. When no correctable lesion is found, an examination of frozen sections obtained from the transected porta hepatis can detect the presence of biliary epithelium and determine the size and patency of the residual bile ducts. In some cases, the cholangiogram indicates that the

biliary tree is patent but of diminished caliber, suggesting that the cholestasis is not due to biliary tract obliteration but to bile duct paucity or markedly diminished flow in the presence of intrahepatic disease. In these cases, transection of or further dissection into the porta hepatis should be *avoided*.

For patients in whom no correctable lesion is found, the hepatoportoenterostomy procedure of Kasai can be carried out. The rationale for this operation is that minute bile duct remnants, representing residual channels, may be present in the fibrous tissue of the porta hepatis; such channels may be in direct continuity with the intrahepatic ductule system. In such cases, transection of the porta hepatis with anastomosis of bowel mucosa to the proximal surface of the transection may allow bile drainage. If flow is not rapidly established within the first months of life, progressive obliteration and cirrhosis ensue. If microscopic channels of patency greater than 150?µm in diameter are found, postoperative establishment of bile flow is likely. The success rate for establishing good bile flow following the Kasai operation is much higher (90%) if performed before 8 wk of life. Therefore, the importance of early referral and prompt evaluation of infants with suspected biliary atresia is emphasized.

Some patients with biliary atresia, even of the “non-correctable” type, derive long-term benefits from interventions such as the Kasai procedure. In most, however, a degree of hepatic dysfunction persists. Patients with biliary atresia usually have persistent inflammation of the intrahepatic biliary tree, which suggests that biliary atresia reflects a dynamic process involving the entire hepatobiliary system. This may account for the ultimate development of complications such as portal hypertension. The short-term benefit of hepatoportoenterostomy is decompression and drainage sufficient to forestall the onset of cirrhosis and sustain growth until a successful liver transplantation can be done (Chapter 349).

MANAGEMENT OF CHRONIC CHOLESTASIS

With any form of neonatal cholestasis, whether the primary disease is idiopathic neonatal hepatitis, intrahepatic bile duct paucity, or biliary atresia, affected patients are at increased risk for chronic complications. These reflect various degrees of residual hepatic functional capacity and are due directly or indirectly to diminished bile flow:

1. Any substance normally excreted into bile is retained in the liver, with subsequent accumulation in tissue and in serum. Involved substances include bile acids, bilirubin, cholesterol, and trace elements.
2. Decreased delivery of bile acids to the proximal intestine leads to inadequate digestion and absorption of dietary long-chain triglycerides and fat-soluble vitamins.
3. Impairment of hepatic metabolic function may alter hormonal balance and utilization of nutrients.
4. Progressive liver damage may lead to biliary cirrhosis, portal hypertension, and liver failure.

Treatment of such patients (Table 337–3) is empirical, and is guided by careful monitoring. No therapy is known to be effective in halting the progression of cholestasis or in preventing further hepatocellular damage and cirrhosis.

Growth failure is a major concern and is related in part to malabsorption and malnutrition resulting from ineffective digestion and absorption of dietary fat. Use of a medium-chain triglyceride–containing formula may improve caloric balance.

With chronic cholestasis and prolonged survival, children with hepatobiliary disease may experience deficiencies of the fat-soluble vitamins (A, D, E, and K). Inadequate absorption of fat and fat-soluble vitamins may be exacerbated by administration of the bile acid binder cholestyramine. Metabolic bone disease is common.

Serum vitamin A concentration can usually be maintained at normal levels in patients who have chronic cholestasis and who received oral supplementation of vitamin A esters. It is essential to monitor the vitamin A status in such patients.

A degenerative neuromuscular syndrome is found with chronic cholestasis caused by malabsorption and vitamin E deficiency; affected children experience progressive areflexia, cerebellar ataxia, ophthalmoplegia, and decreased vibratory sensation. Specific morphologic lesions have been found in the central nervous system, peripheral nerves, and muscles. These lesions are potentially reversible in young children (<3–4 yr old). Affected children have low serum vitamin E concentrations, increased hydrogen peroxide hemolysis, and low ratios of serum vitamin E to total serum lipids (<0.6?mg/g for children younger than 12 yr and <0.8?mg/g for older patients). Vitamin E deficiency may be prevented by oral administration of large

doses (up to 1,000?IU/day); patients unable to absorb sufficient quantities may require administration of d-tocopherol polyethylene glycol-1000 succinate orally. Serum levels may be monitored as a guide to efficacy.

Pruritus is a particularly troublesome complication of chronic cholestasis, often with the appearance of xanthomas. Both features seem to be related to the accumulation of cholesterol and bile acids in serum and in tissues. Elimination of these retained compounds is difficult when bile ducts are obstructed, but if there is any degree of bile duct patency, administration of ursodeoxycholic acid may increase bile flow or interrupt the enterohepatic circulation of bile acids and thus decrease the xanthomas and ameliorate the pruritus (see Table 337–3). Ursodeoxycholic acid therapy may also lower serum cholesterol levels. The recommended dose is 15?mg/kg/24?hr.

Progressive fibrosis and cirrhosis will lead to the development of portal hypertension and consequently to ascites and variceal hemorrhage. The presence of ascites is a risk factor for the development of spontaneous bacterial peritonitis (SBP). The first step in the management of patients with ascites is to rule out SBP and restrict sodium intake to 0.5?g (~1–2?mEq/kg/24?hr). There is no need for fluid restriction in patients with adequate renal output. Should this be ineffective, diuretics may be helpful. The

TABLE 337.1-3 -- **Suggested Medical Management of Persistent Cholestasis**

Clinical Impairment	Management
Malnutrition resulting from malabsorption of dietary long-chain triglycerides	Replace with dietary formula or supplements containing medium-chain triglycerides
Fat-soluble vitamin malabsorption:	
Vitamin A deficiency (night blindness, thick skin)	Replace with 10,000–15,000 IU/day as Aquasol A
Vitamin E deficiency (neuromuscular degeneration)	Replace with 50–400 IU/day as oral a-tocopherol or TPGS
Vitamin D deficiency (metabolic bone disease)	Replace with 5,000–8,000 IU/day of D_2 or 3–5?µg/kg/day of 25-hydroxycholecalciferol
Vitamin K deficiency (hypoprothrombinemia)	Replace with 2.5–5.0 mg every other day as water-soluble derivative of menadione
Micronutrient deficiency	Calcium, phosphate, or zinc supplementation
Deficiency of water-soluble vitamins	Supplement with twice the recommended daily allowance
Retention of biliary constituents such as cholesterol (itch or xanthomas)	Administer choleretic bile acids and ursodeoxycholic acid, 15–20 mg/kg/day
Progressive liver disease; portal hypertension (variceal bleeding, ascites, hypersplenism)	Interim management (control bleeding; salt restriction; spironolactone)
End-stage liver disease (liver failure)	Transplantation

TPGS = D-tocopherol polyethylene glycol-1000 succinate.

diuretic of choice is spironolactone (3–5?mg/kg/24?hr in four doses). If spironolactone alone does not control ascites, the addition of another diuretic such as thiazide or furosemide may be beneficial. Patients with ascites but without peripheral edema are at risk for reduced plasma volume and decreased urine output during diuretic therapy. Tense ascites alters renal blood flow and systemic hemodynamics. Paracentesis and intravenous albumin infusion may improve hemodynamics, renal perfusion, and symptoms. Follow-up includes dietary counseling and monitoring of serum and urinary electrolyte concentrations (Chapter 345 and Chapter 348).

In patients with portal hypertension, variceal hemorrhage and the development of hypersplenism are common. It is important to ascertain the cause of bleeding because episodes of gastrointestinal hemorrhage in patients who have chronic liver disease may be due to gastritis or peptic ulcer disease. Because the management of these various complications differs, differentiation perhaps via endoscopy is necessary before treatment is initiated (Chapter 348). If the patient is volume depleted, blood transfusion should be carefully administered avoiding overtransfusion, which may precipitate further bleeding. The use of balloon tamponade is not recommended in children because it may be associated with significant complications. On the other hand, sclerotherapy or endoscopic variceal ligation may be useful palliative measures in the management of bleeding varices and may be superior to surgical alternatives.

In patients with advanced liver disease, hepatic transplantation may have a success rate greater than 85% (Chapter 349). If the operation is technically feasible, it will prolong life and may correct the metabolic error in diseases such as a_1 -antitrypsin deficiency, tyrosinemia, and Wilson disease. Success depends on adequate intraoperative, preoperative, and postoperative care and on cautious use of immunosuppressive agents. Scarcity of donors of small livers severely limits the application of liver transplantation for infants and children. The use of *reduced*-size transplants and living donors increases the ability to treat small children successfully.

PROGNOSIS

For patients with idiopathic neonatal hepatitis, the variable prognosis may reflect the heterogeneity of the disease. In **sporadic** cases, 60–70% recover with no evidence of hepatic structural or functional impairment. Approximately 5–10% have persistent fibrosis or inflammation, and a smaller percentage have more severe liver disease, such as cirrhosis. Death of infants usually occurs early in the course of the illness, owing to hemorrhage or sepsis. Of infants with idiopathic neonatal hepatitis of the **familial** variety, only 20–30% recover; 10–15% acquire chronic liver disease with cirrhosis. Liver transplantation may be required.

337.2 Cholestasis in the Older Child

Most cases of cholestasis with onset after the neonatal period are due to acute viral hepatitis or drug-induced. Many of the conditions causing neonatal cholestasis may also cause chronic cholestasis in older patients. Adolescents with conjugated hyperbilirubinemia should be evaluated for acute and chronic hepatitis, a_1 -antitrypsin deficiency, Wilson disease, liver disease associated with inflammatory bowel disease, autoimmune hepatitis, and the syndromes of intrahepatic cholestasis (with or without bile duct paucity). Other causes include obstruction caused by cholelithiasis, abdominal tumors, enlarged lymph nodes, or hepatic inflammation resulting from drug ingestion. Management of cholestasis in the older child is similar to that proposed for neonatal cholestasis (see Table 337–3).

Chapter 338 - Metabolic Diseases of the Liver

Jeffrey A. Rudolph
William F. Balistreri

See also Chapter 73 and Chapter 91.3 .

Because the liver has a central role in synthetic, degradative, and regulatory pathways involving carbohydrate, protein, lipid, trace element, and vitamin metabolism, many metabolic abnormalities or specific enzyme deficiencies affect the liver primarily or secondarily (Box 338–1). Liver disease may arise when absence of an enzyme produces a block in a metabolic pathway, when unmetabolized substrate accumulates proximal to a block, when deficiency of an essential substance produced distal to an aberrant chemical reaction develops, or when synthesis of an abnormal metabolite occurs. The spectrum of pathologic

CPS = Carbamoyl phosphate synthetase; OTC = ornithine transcarbamoylase; N-AGS = *N*-acetylglutamate synthetase.

*See chapters in parentheses.

changes includes (1) *hepatocyte injury,* with subsequent failure of other metabolic functions, often eventuating in cirrhosis, liver tumors, or both; (2) *storage* of lipid, glycogen, or other products manifested as hepatomegaly, often with complications specific to deranged metabolism (decreased blood glucose in patients with glycogen storage disease); and (3) absence of structural change despite profound metabolic effects, as with urea cycle defects. The clinical manifestations of metabolic diseases of the liver mimic infections, intoxications, and hematologic and immunologic diseases (Box 338–2). Further clues are provided by family history of a similar illness or by the observation that the onset of symptoms is closely associated with a change in dietary habits (initiation of ingestion of fructose). In most cases, clinical and laboratory evidence guide the evaluation. Liver biopsy offers morphologic study and permits enzyme assays, as well as quantitative and qualitative assays of various other constituents. Such studies require cooperation of experienced laboratories and careful attention to collection and handling of specimens.

Box 338-2. Clinical Manifestations That Suggest the Possibility of Metabolic Disease

- Recurrent vomiting, failure to thrive, short stature, dysmorphic features
- Jaundice, hepatomegaly (± splenomegaly), fulminant hepatic failure
- Hypoglycemia, organic acidemia, lactic acidemia, hyperammonemia, bleeding (coagulopathy)
- Recurrent vomiting, failure to thrive, short stature, dysmorphic features
- Developmental delay/psychomotor retardation, hypotonia, progressive neuromuscular deterioration, seizures
- Cardiac dysfunction/failure, unusual odors, rickets, cataracts

338.1 Inherited Deficient Conjugation of Bilirubin (Familial Nonhemolytic Unconjugated Hyperbilirubinemia)

Hepatic glucuronyl transferase activity (Chapter 91.3) is deficient in two genetically and functionally distinct disorders (Crigler-Najjar syndromes, type I and II), producing congenital nonobstructive, nonhemolytic, unconjugated hyperbilirubinemia. The molecular mechanism of the various Crigler-Najjar syndromes is complex. This is partly because the activity of multiple glucuronyl transferase isoforms is deficient in various phenotypes of the Crigler-Najjar syndrome. Low enzyme levels with unconjugated hyperbilirubinemia also occur in **Gilbert syndrome**, a benign disorder, commonly caused by a polymorphism in the promoter region of the transferase gene.

Crigler-Najjar Syndrome (Type I Glucuronyl Transferase Deficiency).

This form is inherited as an autosomal recessive trait and is due to mutations in the UDP(B)-GT gene. Parents of affected children have partial defects in conjugation as determined by hepatic enzyme assay or by measurement of glucuronide formation, but their serum bilirubin concentrations are normal.

CLINICAL MANIFESTATIONS.

Severe unconjugated hyperbilirubinemia develops in homozygous infants during the first 3 days of life, and without treatment, serum concentrations of 25–35?mg/dL are reached during the 1st mo. Kernicterus, an almost universal complication of this disorder, is usually first noted in the early neonatal period, but some treated infants have survived childhood without clinical sequelae. Stools are pale yellow. Persistence of unconjugated hyperbilirubinema at levels above 20?mg/dL after the 1st wk of life in the absence of hemolysis should suggest the syndrome.

DIAGNOSIS.

The diagnosis of Crigler-Najjar syndrome is based on the early age of onset and the extreme level of bilirubin elevation in the absence of hemolysis. In the bile, bilirubin concentration is less than 10?mg/dL compared with normal concentrations of 50–100?mg/dL, and there is no bilirubin glucuronide. Definitive diagnosis is established by measuring

hepatic glucuronyl transferase activity in a liver specimen obtained by a closed biopsy; open biopsy should be avoided because surgery and anesthesia may precipitate kernicterus. DNA diagnosis is also available. Identification of the heterozygous state in the parents is also strongly suggestive of the diagnosis. Differential diagnosis is discussed in Chapter 91.3 . Type II disease may be distinguished from type I by the marked decline in serum bilirubin level that occurs in type II disease after 1 wk of treatment with phenobarbital.

TREATMENT.

Serum bilirubin concentration should be kept below 20?mg/dL for at least the first 2–4 wk of life; in low birthweight infants, the levels should be kept lower. This usually requires repeated exchange transfusions and phototherapy. Phenobarbital therapy

should be considered to determine responsiveness and differentiation between type I and II. Because the risk of kernicterus persists into adult life, although the serum bilirubin levels required to produce brain injury beyond the neonatal period are considerably higher (usually >35?mg/dL), phototherapy is generally continued throughout the early years of life. In older infants and children, phototherapy is used mainly during sleep in order not to interfere with normal activities. However, despite the administration of increasing intensities of light for longer periods, the serum bilirubin decrement response to phototherapy decreases with age. Adjuvant therapy using agents that bind photobilirubin products such as calcium phosphate, cholestyramine, or agar may be used to interfere with the enterohepatic recirculation of bilirubin. Prompt treatment of intercurrent infections, febrile episodes, and other types of illness may help prevent the later development of kernicterus, which may occur at bilirubin levels of 45–55?mg/dL. All patients with type I have eventually experienced severe kernicterus by young adulthood, despite vigorous continuous management that maintained neurologic normality during childhood. Orthotopic hepatic transplantation cures the disease and has been successful in a small number of patients, and isolated hepatocyte transplantation has been reported in one patient. Other therapeutic modalities have included plasmapheresis and limitation of bilirubin production. The latter option, inhibiting bilirubin generation, is possible via inhibition of heme oxygenase using metalloporphyrin therapy. Genetically engineered enzymatic replacement therapy and liver-directed gene therapy remain potential therapeutic options in the future.

Crigler-Najjar Syndrome (Type II Glucuronyl Transferase Deficiency).

This autosomal dominant disease with marked variability of penetrance may present in a manner similar to type I syndrome, or it may be a less severe disorder, occasionally even without neonatal manifestations. Crigler-Najjar syndrome type II is caused by homozygous missense mutation in glucuronyl transferase isoform I resulting in only partial enzymatic activity.

CLINICAL MANIFESTATIONS.

When this disorder presents in the neonatal period, unconjugated hyperbilirubinemia usually occurs during the first 3 days of life; serum bilirubin concentrations may be in a range compatible with physiologic jaundice or may be at pathologic levels. The concentrations characteristically remain elevated into and after the 3rd wk of life, persisting in a range of 1.5–22?mg/dL; concentrations in the lower part of this range may create uncertainty about whether chronic hyperbilirubinemia is present. The onset of kernicterus is unusual. Stool color is normal, and the infants are without clinical signs or symptoms of disease. There is no evidence of hemolysis.

DIAGNOSIS.

Concentration of bilirubin in bile is nearly normal in type II syndrome. Jaundiced infants and young children having type II syndrome respond readily to 5?mg/kg/24?hr of oral phenobarbital with a decrease in serum bilirubin concentration to 2–3?mg/dL within 7–10 days. Those with type I syndrome do not respond.

TREATMENT.

Long-term reduction in serum bilirubin levels can be achieved with continued administration of phenobarbital at 5?mg/kg/24?hr. The cosmetic and psychosocial benefit should be weighed against the risks of an effective dose of the drug because there is a small long-term risk of kernicterus in the absence of hemolytic disease.

INHERITED CONJUGATED HYPERBILIRUBINEMIA

In inherited conjugated hyperbilirubinemias (see also Chapter 337), which are autosomal recessive disorders characterized by mild jaundice, the transfer of bilirubin and other organic anions from liver to bile is defective. Chronic mild conjugated hyperbilirubinemia is usually detected during adolescence or early adulthood but may occur as early as the 2nd year of life. The results of routine liver function tests are normal. Jaundice may be exacerbated with infection, pregnancy, oral contraceptives, alcohol consumption, or surgery. There is usually no morbidity, and life expectancy is normal; but these disorders may initially present difficult problems in the differential diagnosis of more serious diseases.

Dubin-Johnson Syndrome.

Dubin-Johnson syndrome is considered to be an autosomal recessive inherited defect in hepatocyte secretion of bilirubin glucuronide. The defect in hepatic excretory function is not limited to conjugated bilirubin excretion but also involves several organic anions normally excreted from the liver cell into bile. Absent function of multiple drug-resistant protein (MRP2), an adenosine triphosphate (ATP)-dependent canalicular transporter, is the responsible defect. Bile acid excretion is normal, and serum bile acid levels are normal. Urinary coproporphyrin excretion is normal in quantity; however, due to a defect in porphyrin excretion, coproporphyrin I constitutes 80% of the total. Coproporphyrin III is normally greater than 75% of the total. Cholangiography fails to visualize the biliary tract and roentgenography of the gallbladder is also abnormal. The liver cells contain black pigment similar to melanin.

Rotor Syndrome.

These patients have an additional deficiency in organic anion uptake. Total urinary coproporphyrin excretion is elevated, with a relative increase in the amount of the coproporphyrin I isomer. The gallbladder is normal by roentgenography, and liver cells contain no black pigment. Sulfobromophthalein excretion is often abnormal.

338.2 Wilson Disease

Wilson disease (hepatolenticular degeneration) is an autosomal recessive disorder characterized by degenerative changes in the brain, liver disease, and Kayser-Fleischer rings in the cornea (Chapter 592). The incidence is 1/500,000–100,000 births. It is fatal if untreated; however, specific effective treatment is available. Rapid diagnostic investigation of the possibility of Wilson disease in a patient presenting with any form of liver disease, particularly if older than 5 yr, not only facilitates early institution of management of Wilson disease and related genetic counseling but also allows appropriate treatment of non-Wilson liver

disease once copper toxicosis is ruled out.

Pathogenesis.

Defective mobilization of copper from lysosomes in liver cells for excretion into bile is the basis for the multiorgan damage in patients with Wilson disease. Relentless accumulation of copper in the liver reaches the point at which the retention capacity is exceeded. Copper then escapes the liver to damage other organs, particularly the brain and kidneys, and accumulates in the cornea, visible as Kayser-Fleischer rings. The underlying mechanism of liver damage in Wilson disease is presumably oxidant injury to the hepatocyte mitochondria, which is the target organelle in copper-induced toxicity. Lipid peroxidation of the mitochondria resulting from copper overload leads to functional alterations.

The abnormal gene for Wilson disease is on chromosome 13; linkage studies have assigned the Wilson disease locus to chromosome 13 at q14–q21. The gene encodes amino acid structural motifs consistent with a role in copper transport. The Wilson disease gene, like the Menkes disease gene, is predicted to encode a copper-binding, cation-transporting P-type ATPase and acts as a copper pump with ATP as an energy source. More than 100 mutations in the gene have been identified, making diagnosis by DNA mutational analysis a difficult task unless a proband mutation is known. Mutations that completely destroy gene function are associated with an onset of disease symptoms as early as 2–3 yr of age, when Wilson's disease may not typically be considered in the differential diagnosis. Milder mutations can be associated with neurologic symptoms or liver disease as late as 50 yr of age. Cloning of the gene for Wilson disease raises the prospect of precise presymptomatic detection of Wilson disease, timely initiation of therapy, and ultimately gene therapy.

Fetal and neonatal liver normally contains relatively high concentrations of sulfur-rich copper-binding protein (metallothionein) and of copper; serum ceruloplasmin and copper levels are relatively low. The mechanisms responsible for copper homeostasis in older children reach maturity by 2 yr of age. The wilsonian trait may be expressed after this time, but Wilson disease is not clinically manifested before age 5 yr.

Altered incorporation of copper into hepatic proteins such as ceruloplasmin is associated with diffuse accumulation of copper in the cytosol of hepatocytes. Later, as liver cells are overloaded, copper is distributed to other tissues, to which it is toxic, primarily as a potent inhibitor of enzymatic processes. Ionic copper inhibits pyruvate oxidase in brain and ATPase in membranes, leading to decreased ATP-phosphocreatine and potassium content of tissue. The glycolytic pathway and microsomal membrane ATPases are inhibited.

Clinical Manifestations.

Copper enters the circulation in a non-ceruloplasmin-bound form and accumulates in many organs, inducing injury resulting in the various symptoms of Wilson disease. Manifestations are variable, with a tendency to familial patterns. The younger the patient, the more likely hepatic involvement will be the predominant manifestation. After 20 yr of age, neurologic symptoms predominate. Forms of hepatic disease include asymptomatic hepatomegaly (with or without splenomegaly), subacute or chronic hepatitis, and fulminant hepatic failure. Cryptogenic cirrhosis, portal hypertension, ascites, edema, variceal bleeding, or other effects of hepatic dysfunction (delayed puberty, amenorrhea, or coagulation defect) may be manifestations of Wilson disease.

Neurologic and psychiatric disorders may develop insidiously or precipitously, with intention tremor, dysarthria, dystonia, deterioration in school performance, or behavioral changes. Kayser-Fleischer rings may be absent in young patients with liver disease but are always present in patients with neurologic symptoms. Hemolysis may be an initial manifestation, possibly related to the release of large amounts of copper from damaged hepatocytes; this form of Wilson disease is usually fatal without transplantation. During hemolytic episodes, urinary copper excretion and serum copper levels (non-ceruloplasmin-bound) are markedly elevated. Manifestations of Fanconi syndrome and progressive renal failure with alterations in tubular transport of amino acids, glucose, and uric acid may be present. Unusual manifestations include arthritis and endocrinopathies, such as hypoparathyroidism.

Pathology.

All grades of hepatic injury occur, with fatty change, ballooned hepatocytes, glycogen granules, minimal inflammation, and enlarged Kupffer cells. The lesion may be indistinguishable from that of chronic hepatitis. Ultrastructural changes include large, dense mitochondria with altered smooth endoplasmic reticulum.

Diagnosis.

Wilson disease should be considered in children and teenagers with unexplained acute or chronic liver disease, neurologic symptoms of unknown cause, acute hemolysis, psychiatric illnesses, behavioral changes, Fanconi syndrome, or unexplained bone disease. The clinical suspicion is confirmed by study of indices of copper metabolism.

The best screening test is to measure the serum ceruloplasmin level. Most patients with Wilson disease have decreased ceruloplasmin levels. Serum copper level may be elevated in early Wilson disease, and urinary copper excretion (usually <40?µg/day) is increased to greater than 100?µg/day and often up to 1,000?µg or more per day. In equivocal cases, the response of urinary copper output to chelation may be of diagnostic help; after a 1-g oral dose of d-penicillamine, affected patients excrete 1,200–2,000?µg/24?hr.

Liver biopsy is of value for examination of the histology and for measurement of the hepatic copper content (normally <10?µg/g dry weight). In Wilson disease, hepatic copper content exceeds 250?µg/g dry weight. In healthy heterozygotes, levels may be intermediate.

Family members of patients with proven cases require screening for presymptomatic

Wilson disease. Such screening should include determination of the serum ceruloplasmin level and urinary copper excretion. If these results are abnormal or equivocal, liver biopsy should be carried out to determine morphology and hepatic copper content. Genetic screening by either linkage analysis or direct DNA mutation analysis is possible, especially if the mutation for the proband case is known.

Treatment.

Administration of copper-chelating agents leads to rapid excretion of excess deposited copper in patients with Wilson disease. A major attempt should be made to restrict copper intake to less than 1?mg/day. Foods such as liver, shellfish, nuts, and chocolate should be avoided. If the copper content of the water exceeds 0.1?mg/L, it may be necessary to demineralize the water. Chelation therapy is currently best managed with oral administration of penicillamine (ß, ß-dimethylcysteine) in a dose of 1?g/day in two doses before meals for adults and 0.5–0.75?g/day for patients younger than 10 yr. In response to d-penicillamine, urinary copper excretion markedly increases and there may be slow clinical improvement. Urinary copper levels may become normal with continued administration of d-penicillamine, with marked improvement in hepatic and neurologic function and the disappearance of Kayser-Fleischer rings. Toxic effects of penicillamine are uncommon and consist of hypersensitivity reactions (Goodpasture syndrome, systemic lupus erythematosus, polymyositis), interaction with collagen and elastin, deficiency of other elements such as zinc, as well as aplastic anemia and nephrosis. Because penicillamine is an antimetabolite of vitamin B_6 , additional amounts of this vitamin are necessary. For those patients who are unable to tolerate penicillamine, triethylene tetramine dihydrochloride (Trien, TETA, trientine) at a dose of 0.5–2?g/24?hr is an acceptable alternative. Zinc has also been used as adjuvant therapy or as maintenance therapy owing to its unique ability to impair the gastrointestinal absorption of copper. Zinc acetate is given in adults at a dose of 25 to 50?mg three times a day. Pediatric dosing guidelines have not been established.

Prognosis.

Untreated patients with Wilson disease die of the hepatic, neurologic, renal, or hematologic complications. The prognosis for patients receiving prompt and continuous d- penicillamine is variable and depends on the time of initiation of and the individual responsiveness to chelation. Liver transplantation should be considered for patients with fulminant liver disease, decompensated cirrhosis, or progressive neurologic disease; the latter indication remains controversial. In asymptomatic siblings of affected patients, early institution of chelation therapy can prevent expression of the disease.

338.3 Hepatic Copper Overload Syndrome

Another form of childhood cirrhosis apparently associated with a genetic disturbance in copper metabolism has been described. This syndrome differs from Wilson disease in its earlier onset. Affected children experience progressive lethargy, abdominal distention, and jaundice and die before 6 yr of age. The hepatic histopathology resembles that of Indian childhood cirrhosis. Variants of this syndrome have been named according to the population where it has been described, such as Tyrolean childhood cirrhosis and North American Indian cirrhosis.

338.4 Indian Childhood Cirrhosis

Indian childhood cirrhosis is a fatal familial disorder that occurs predominantly in rural India in middle income Hindu families. It has been reported also in the Middle East, in West Africa, and in Central America. It affects children of both sexes, with onset usually at 1–3 yr of age. Hepatomegaly is often the first sign; fever, anorexia, and jaundice occur. There is in most cases rapid evolution to cirrhosis and liver failure. Serum immunoglobulin levels and hepatic copper concentrations are markedly elevated. No effective therapy is known.

It has been suggested that excessive dietary copper may have a role in the cause, owing to the use of copper and brass in cooking and for storage of water and milk. However, there may be a predisposing inherited susceptibility. Early introduction of copper-contaminated milk into infant diets may explain the epidemiologic features.

338.5 Neonatal Iron Storage Disease (NISD)

NISD is a rare form of fulminant liver disease of unknown cause characterized by diffuse increased iron deposition in the liver, pancreas, heart, and endocrine organs without evidence of increased iron intake (ingestion or transfusion). Inheritance may be autosomal recessive in some cases. Affected infants may be born prematurely, or with intrauterine growth retardation. A large placenta is found, and a rapidly fatal progressive illness characterized by hepatomegaly, hypoglycemia, hypoprothrombinemia, hypoalbuminemia, and hyperbilirubinemia follows. Symptoms begin in utero or in the 1st wk of life. The coagulopathy is refractory to therapy with vitamin K. The diagnosis can be confirmed through documentation of extrahepatic siderosis (biopsy material of buccal mucosal glands is laden with iron) or magnetic resonance imaging determination of iron storage in organs such as the pancreas.

The hepatic pathology reveals fibrosis, regenerative nodules, giant cell formation, necrosis, and hepatocellular hemosiderin deposits not unlike those in adult-type hereditary hemochromatosis. Hyperferritinemia is present.

Treatment with chelating agents (deferoxamine) alone is ineffective. Preliminary studies suggest that aggressive antioxidant therapy, combined with iron chelation, may be effective if initiated very early. Liver transplantation should also be an early consideration.

338.5 Miscellaneous Metabolic Diseases of the Liver

a-ANTITRYPSIN DEFICIENCY

A small percentage of individuals homozygous for deficiency of the major serum protease inhibitor, a_1 -antitrypsin, have neonatal cholestasis and later childhood cirrhosis (see also Chapter 393.4). a_1 -Antitrypsin, a protease inhibitor synthesized

by the liver, accounts for 80% of the serum a_1 -globulin fraction. a_1 -Antitrypsin is present in more than 20 different co-dominant alleles, only a few of which are associated with defective protease inhibitors. The most common allele of the protease inhibitor (Pi) system is M, and the normal phenotype is PiMM. The Z allele predisposes to clinical deficiency; patients with liver disease are usually PiZZ and have serum a_1 -antitrypsin levels less than 2?mg/mL (approximately 10–20% of normal). The incidence of the PiZZ genotype in the white population is estimated at 1/2,000–4,000. Intermediate phenotypes PiMS, PiMZ, and PiSZ are not definitively associated with liver disease. The null genotype has no periodic acid-Schiff (PAS)-positive inclusions and is not associated with liver disease. Of all PiZZ persons, fewer than 20% develop neonatal cholestasis. These patients are indistinguishable from other infants with “idiopathic” neonatal hepatitis, of whom they constitute approximately 5–10%.

In affected patients, the course of liver disease is highly variable. Jaundice, acholic stools, and hepatomegaly are present during the 1st wk of life, but the jaundice usually clears during the 2nd–4th mo. Complete resolution, persistent liver disease, or the development of cirrhosis may follow. Older children may present with manifestations of chronic liver disease or cirrhosis, with evidence of portal hypertension.

The fact that liver disease is not universal suggests a complex pathogenesis. The liver disease may be secondary to retention of a_1 -antitrypsin in the liver with failure of degradation.

The diagnosis is best made by determination of an a_1 -antitrypsin (Pi) phenotype and confirmed by liver biopsy. PAS-positive disease-resistant intracytoplasmic globules are seen in periportal hepatocytes. Immunofluorescence and immunocytochemical studies have shown this material to be antigenically related to a_1 -antitrypsin. It has been suggested that abnormal biosynthesis of the protein or defective glycosylation may interfere with excretion of the product from the rough endoplasmic reticulum into the extracellular space. Electron microscopy shows amorphous deposits (glycoprotein) within dilated rough endoplasmic reticulum.

The pattern of neonatal liver injury may be highly variable. Hepatocellular damage with giant cell transformation, minimal inflammation, and bile stasis may be noted. Various degrees of portal fibrosis with biliary duct proliferation occur.

Liver transplantation has been curative. There is no other effective therapy for liver disease yet, but in the future, gene therapy will be possible.

CYSTIC FIBROSIS

Cystic fibrosis (CF) (see also Chapter 402) is a multiorgan disease caused by a mutation in the cystic fibrosis transmembrane conductance regulator (CFTR) gene, a cAMP dependent chloride transporter found in epithelial cells. The cholangiocytes, which line the bile ducts of the liver, express CFTR to enable electrolyte transport necessary for the efficient flow of bile. Therefore, cystic fibrosis is a defect of the cholangiocytes. Liver disease may affect from 17 to 25% of all CF patients. The liver lesions include cholestasis, steatosis, focal biliary cirrhosis, multilobular cirrhosis, and biliary tract abnormalities such as microgallbladder and gallstones. Diagnosis of liver disease in CF is made by biochemical analysis, hepatic ultrasound, or liver biopsy in patients with a positive sweat test or known genetic mutation of CFTR. Liver biopsy is controversial in that there is no curative therapy and should be considered only to stage fibrosis or exclude other lesions. Although no therapy has proved useful to reverse liver disease, ursodeoxycholic acid, given at a dose of 10–15?mg/kg/day has been shown to improve bile flow.

NONALCOHOLIC STEATOHEPATITIS

Obesity may lead to nonalcoholic steatohepatitis (NASH; see also Chapter 43), an acquired metabolic disease of the liver characterized by steatosis, and in some cases, inflammation and fibrosis. The pathogenic mechanisms leading to NASH are not well characterized but may involve increased oxidative stress leading to adipose tissue synthesis of tumor necrosis factor and activation of hepatic stellate cells resulting in increased deposition of extracellular matrix leading to inflammation and fibrosis. NASH appears to be associated with obesity, insulin resistance, and hyperlipidemia. Patients are often asymptomatic but will have hepatomegaly. Diagnosis can be made by an elevation of aminotransaminase levels (aspartate aminotransferase > alanine aminotransferase), ultrasound changes suggestive of fat accumulation, and the exclusion of infectious, toxic, or metabolic causes. Other causes of fatty liver disease include intestinal bypass surgery for obesity, drugs (steroids, estrogens, valproic acid, zidovudine, methotrexate, tetracycline, aspirin), pregnancy, lipid metabolic disorders, hepatotoxins, human immunodeficiency virus, and inflammatory bowel disease. Liver biopsy can be considered, but is not necessary as long as other etiologies for fatty accumulation can be discarded. Treatment consists of dietary counseling; improvement has been noted in patients after weight reduction or vitamin E therapy. Attempts to manage patients with diet often fail and the symptoms persist.

Chapter 339 - Viral Hepatitis

John D. Snyder
Larry K. Pickering

Viral hepatitis is a major health problem in developing and developed countries. Hepatotropic viruses are designated hepatitis A, B, C, D, E, and G viruses (Table 339–1). Many other viruses can cause hepatitis as one component of a multisystem disease, including herpes simplex virus (HSV), cytomegalovirus (CMV), Epstein-Barr virus, varicella-zoster virus, human immunodeficiency virus (HIV), rubella, adenoviruses, enteroviruses, parvovirus B19, and arboviruses.

The six hepatotropic viruses are a heterogeneous group that cause similar acute clinical illness, except for HGV, which appears to cause no or mild disease. HBV is a DNA virus, whereas HAV, HCV, HDV, HEV, and HGV are RNA viruses representing four different families (Table 339–2). HAV and HEV are not known to cause chronic illness, whereas HBV, HCV, and HDV viruses can cause important morbidity and mortality through chronic infections. HGV can cause chronic infections but with little morbidity or mortality yet reported. In the United States, HAV appears to cause most cases of hepatitis in children. HBV probably accounts for about one third of symptomatic cases in children, whereas HCV is found in approximately 20%. HDV, which occurs only in the presence of HBV, occurs in only a small percentage of children. HEV has not been reported in children who have lived and traveled only in the United States. HGV's role is not yet completely known, but the virus appears to account for a small percentage of cases of non–HAV-HEV infections.

Differential Diagnosis.

The probable causes of hepatitis vary somewhat by age. In the newborn period, infection remains an important cause of hyperbilirubinemia but metabolic and anatomic causes (e.g., biliary atresia and choledochal cysts) also must be considered. The introduction of pigmented vegetables into an infant's diet may result in carotenemia, which may be mistaken for jaundice.

In later infancy and childhood, hemolytic-uremic syndrome may be initially mistaken for hepatitis (Chapter 449). Reye and Reye-like syndromes present in a similar fashion to acute fulminating hepatitis (Chapter 342). Jaundice also may occur with malaria, leptospirosis, and brucellosis and with severe infection in older children, particularly in children with malignancy or immunodeficiency. Gallstones may obstruct biliary drainage and cause jaundice in adolescents as well as in children with chronic hemolytic processes. Hepatitis may be the initial presentation of Wilson disease, cystic fibrosis, and Jamaican vomiting sickness. The liver may also be involved in collagen diseases including systemic lupus erythematosus.

TABLE 339-1 -- Viral Hepatitis Nomenclature

Hepatotropic Viruses	Antigens	Identified Antibodies
Hepatitis A virus (HAV)	HAV	anti-HAV* IgM anti-HAV
Hepatitis B virus (HBV)	HBsAg*	anti-HBsAg*
		IgM anti-HBsAg*
	HBcAg	anti-HBcAg*
	HBeAg*	anti-HBeAg*
Hepatitis C virus (HCV)		anti-HCV*
Hepatitis D virus (HDV)	HDAg	anti-HDV*
Hepatitis E virus (HEV)		anti-HEV
		IgM anti-HEV
Hepatitis G virus (HGV)		anti-HGV

**Assays are commercially available.*

TABLE 339-2 -- Features of the Six Hepatotropic Viruses

	HAV	HBV	HCV	HDV	HEV	HGV
Nucleic acid	RNA	DNA	RNA	RNA	RNA	RNA
Incubation (mean)	30 days	100–120 days	7–9 wk	2–4 mo	40 days	Unknown
Transmission						
Percutaneous	Rare	Common	Common	Common	No	Common
Fecal-oral	Common	No	No	No	Common	No

Sexual	Rare	Common	Rare	Rare	Rare	Rare
Transplacental	No	Common	Rare	No	Probably no	Rare
Chronic infection	No	Yes	Yes	Yes	No	Yes
Fulminant disease	Rare	Yes	Rare	Yes	Rare	Probably no

Medications, including acetaminophen overdose, valproic acid, and various hepatotoxins, including long-acting mushroom toxins, can be associated with a hepatitis-like picture (Chapter 344). Drugs well tolerated in healthy children may cause problems in children with certain illnesses.

HEPATITIS A

Etiology.

HAV is a 27-nm-diameter, RNA-containing virus that is a member of the Picornavirus family. Acute infection is diagnosed by detecting immunoglobulin M (IgM) antibodies (anti-HAV) by radioimmunoassay or, rarely, by identifying viral particles in stool.

Epidemiology.

HAV infections occur throughout the world but are found most commonly in developing countries, where the prevalence rate approaches 100% in children by 5 yr of age. In the United States, approximately 30–40% of the adult population has evidence for previous HAV infection, with the rates of infection being similar in the first, second, and third decades of life. Hepatitis A causes only acute hepatitis and accounts for approximately 50% of clinically apparent acute viral hepatitis in the United States. Most infections in children younger than 5 yr of age are asymptomatic or have mild, nonspecific manifestations; the illness is much more likely to be symptomatic in adults than in children. Prior to 1997, approximately half of cases in the United States occurred in 11 western states (Alaska, Arizona, California, Idaho, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Utah, and Washington), which account for only 22% of the population, with prevalence rates of =20 cases/100,000 population. With routine hepatitis A vaccination in these and all or part of 6 other states (Arkansas, Colorado, Missouri, Montana, Texas, and Wyoming) with intermediate prevalence of 10–20 cases/100,000 population, the incidence is changing, with many eastern and southern states now showing the highest rates of HAV in the United States.

Transmission of HAV is almost always by person-to-person contact. Spread is predominantly by the fecal-oral route; percutaneous transmission occurs rarely, and maternal-neonatal transmission is not recognized. HAV infection during pregnancy or at the time of delivery does not appear to result in increased complications of pregnancy or increased clinical disease in the newborn. The infectivity of human saliva, urine, and semen is unknown. In the United States, increased risk of infection is found in contacts of infected persons, child-care centers, household contacts of children in child care, and homosexual populations and is associated with contact with contaminated food or water and travel to endemic areas. However, no known source is found in about half of the cases. Common source food-borne and water-borne outbreaks have occurred, including several due to contaminated shellfish, frozen berries, and raw produce. Fecal excretion of the virus occurs late in the incubation period, reaches its peak just before the onset of symptoms, and is minimal in the week after the onset of jaundice (Fig. 339–1). The mean incubation period for HAV is about 4 wk, with a range of 15–50 days.

Pathogenesis.

The acute response of the liver to HAV is similar to that of the other hepatotropic viruses (HBV-HEV). The entire liver is involved with necrosis, most markedly in the centrilobular areas, and increased cellularity, which is predominant in the portal areas. The lobular architecture remains intact, although balloon degeneration and necrosis of single or groups of parenchymal cells occur initially. Fatty change is rare. A diffuse mononuclear cell inflammatory reaction causes expansion in the portal tracts; bile duct proliferation is common, but bile duct damage is not often found. Diffuse Kupffer cell hyperplasia is present in the sinusoids, along with infiltration of polymorphonuclear leukocytes and eosinophils. Neonates respond to hepatic injury by forming giant cells. In fulminant hepatitis, total destruction of the parenchyma occurs, leaving only connective tissue septa. By 3 mo after the onset of acute hepatitis due to HAV, the liver usually is normal morphologically.

Other organ systems can be affected during HAV infection. Regional lymph nodes and the spleen may be enlarged. The bone marrow may be moderately hypoplastic, and aplastic anemia has been reported. Small intestine tissue may show changes in villous structure, and ulceration of the gastrointestinal tract can occur, especially in fatal cases. Acute pancreatitis and myocarditis have been reported rarely, and nephritis, arthritis, vasculitis, and cryoglobulinemia may result from circulating immune complexes.

Injury in acute hepatitis caused by hepatotropic viruses is evidenced in three main ways. The first is a reflection of cytopathic injury to the hepatocytes, which release alanine aminotransferase (ALT, formerly serum glutamic-pyruvic transaminase) and aspartate aminotransferase (AST, formerly serum glutamic-oxaloacetic transaminase) into the bloodstream. ALT is more specific to the liver than AST, which also can be elevated after injury to erythrocytes, skeletal muscle, or myocardial cells. The height of elevation does not correlate with the extent of hepatocellular necrosis and has little prognostic value. In some cases, a

Figure 339-1 Pattern of response to hepatitis A virus (HAV) infection. (IgM = immunoglobulin M; IgG = immunoglobulin G.)

falling aminotransferase level may predict a poor outcome if the decline occurs in conjunction with a rising bilirubin level and prolonged prothrombin time (PT). This combination of findings indicates that massive hepatic injury has occurred, resulting

in few functioning hepatocytes. Another enzyme, lactic dehydrogenase (LDH), is even less specific to liver than AST and usually is not helpful in evaluating liver injury. The second mechanism of injury in viral hepatitis results from cholestatic jaundice, in which both direct and indirect bilirubin levels are elevated. Jaundice results from obstruction of biliary flow and damage to hepatocytes. Elevations of serum alkaline phosphatase (ALP), 5'-nucleotidase, ?-glutamyl transpeptidase (GGT), and urobilinogen all can reflect injury to the biliary system. Abnormal protein synthesis is reflected by increased PT. Because of the short half-life of these proteins, the PT is a sensitive indicator of damage to the liver. Serum albumin is another liver-manufactured serum protein, but its longer half-life limits its role in monitoring acute liver injury. Cholestasis results in a decreased intestinal bile acid pool and decreased absorption of fat-soluble vitamins. The third mechanism of hepatic injury by HAV is related to changes that occur in carbohydrate, ammonia, and drug metabolism. Although circulating immune complexes commonly occur in HAV infection, no direct evidence shows that they induce hepatic necrosis or viral clearance.

Clinical Manifestations.

The onset of HAV infection usually is abrupt and is accompanied by systemic complaints of fever, malaise, nausea, emesis, anorexia, and abdominal discomfort. This prodrome may be mild and often goes unnoticed in infants and preschool-aged children. Diarrhea often occurs in children, but constipation is more common in adults. Jaundice may be so subtle in young children that it can be detected only by laboratory tests. When jaundice and dark urine occur, they usually develop after the systemic symptoms. In contrast to infections in children, most HAV infections in adults are symptomatic and can be severe. Symptoms of HAV infection include right upper quadrant pain, dark-colored urine, and jaundice. The duration of symptoms usually is less than 1 mo, and appetite, exercise tolerance, and a feeling of well-being gradually return. Almost all patients with HAV infection recover completely, but a relapsing course can occur for several months. Fulminant hepatitis leading to death is uncommon in children; co-infection with HCV increases the risk for fulminant hepatitis. HAV is not associated with chronic liver disease, persistent viremia, or an intestinal carrier state.

Treatment.

There is no specific treatment for hepatitis A. Most children are asymptomatic or only mildly symptomatic. Treatment is supportive and consists of intravenous hydration as needed.

Diagnosis.

The diagnosis of HAV infection should be considered when a history of jaundice exists in family contacts, friends, schoolmates, or childcare playmates or personnel or if the child or family have traveled to an area endemic for HAV. The diagnosis is established by serologic criteria; liver biopsies rarely are performed. Anti-HAV is detected at the onset of symptoms of acute hepatitis A and persists for life (see Fig. 339–1). The acute infection is diagnosed by the presence of IgM anti-HAV, which is present at the onset of illness and usually disappears within 4 mo but may persist for more than 6 mo. Thereafter, IgG anti-HAV is detectable. IgM antibody is seldom detected after immunization. The virus is excreted in stools from 2 wk before to 1 wk after the onset of illness. Rises are almost universally found in ALT, AST, bilirubin, ALP, 5'-nucleotidase, and GGT and do not help to differentiate the cause. The PT should always be measured in a child with hepatitis to help assess the extent of liver injury; prolongation is a serious sign mandating hospitalization.

Complications.

Children almost universally recover from HAV infections. Rarely, fulminant hepatitis (see Chapter 345) can occur, in which a progressive rise in serum bilirubin is accompanied by an initial rise in aminotransferases followed by a fall to normal or low values despite disease progression. Hepatic synthetic function decreases, and the PT becomes prolonged and is often accompanied by bleeding. The serum albumin level falls, causing edema and ascites. The ammonia level usually rises, and the sensorium becomes altered, progressing from drowsiness to stupor and then deep coma. End-stage disease and death can occur in less than 1 wk or can develop more insidiously.

Prevention.

Persons infected with HAV are contagious for about 7 days after the onset of jaundice and should be excluded from school, child care, or work during this period. Careful handwashing is necessary, particularly after changing diapers and before preparing or serving food. In hospital settings, contact as well as standard precautions, including strict handwashing, are recommended for diapered or incontinent patients for 1 wk after onset of symptoms.

VACCINE.

The availability of two inactivated, highly immunogenic and safe HAV vaccines is having a major impact on the prevention of HAV infection. Both vaccines are approved for children older than 2 yr of age. They are administered intramuscularly in a two-dose schedule, with the second dose given 6–12 mo after the first dose. Seroconversion rates in children exceed 90% after an initial dose and approach 100% after the second dose. The immune response in immunocompromised persons may be suboptimal. HAV vaccine may be administered simultaneously with other vaccines at separate sites. Because the financial, social, and clinical impact of hepatitis A is so substantial in the United States, with indirect costs estimated to be in the hundreds of millions of dollars annually, more widespread vaccination is being recommended. A major obstacle to universal immunization is the lack of a vaccine licensed for children younger than 2 yr of age. Recommended use of HAV vaccine in the United States has been primarily for susceptible persons traveling to or working in countries where HAV is endemic. For persons older than 2 yr of age, vaccine is preferable to immunoglobulin (IG) for pre-exposure prophylaxis (Table 339–3). However, greater consideration is being given to other at-risk groups including (1) children older than 2 yr of age in defined and circumscribed communities with endemic rates or periodic outbreaks of HAV infection (e.g., Native Americans or Alaskan Natives); (2) patients with chronic liver disease; (3) men who have sex with men; (4) users of injection and illicit drugs; (5) individuals at occupational risk of exposure; and (6) persons with clotting factor disorders.

TABLE 339-3 -- Hepatitis A Virus Prophylaxis

Age	Exposure	Dose
Pre-Exposure Prophylaxis (Travelers to Endemic Regions)		
<2 yr	Expected <3 mo	IG 0.02?mL/kg
	Expected 3–5 mo	IG 0.06?mL/kg
	Expected long term	IG 0.06?mL/kg at departure and every 5 mo thereafter
=2 yr	Expected <3 mo	HAV vaccine* or IG 0.02?mL/kg
	Expected 3–5 mo	HAV vaccine* or IG 0.06?mL/kg
	Expected long term	HAV vaccine*
Postexposure Prophylaxis		
	Future exposure likely	
=2 yr	=2 wk since exposure	IG 0.02?mL/kg and HAV vaccine
	>2 wk since exposure	HAV vaccine*
	Future exposure unlikely	
All ages	=2 wk since exposure	IG 0.02?mL/kg and HAV vaccine should be considered (if =2 years)
	>2 wk since exposure	No prophylaxis
IG = immunoglobulin.		

**Two inactivated vaccines are approved for use in persons =2 yr of age.*

IMMUNOGLOBULIN.

Indications for intramuscular administration of IG include pre-exposure and postexposure prophylaxis (see Table 339–3). Intravenous IG (IVIG) is likely to be effective against HAV infection, but appropriate dose, efficacy, and duration of protection have not been defined. IG is recommended for pre-exposure prophylaxis for all susceptible travelers to countries where HAV is endemic. For children older than 2 yr of age, HAV immunization is preferred if the interval before departure is more than 1 mo after dose one. IG as prophylaxis in postexposure situations is used in (1) household and sexual contacts of HAV cases; (2) newborn infants of HAV-infected mothers; (3) child-care center staff, employees, children and their household contacts during an outbreak; and (4) outbreaks in institutions and hospitals. The use of IG more than 2 wk after exposure is not indicated.

IG is not recommended routinely for sporadic nonhousehold exposure (e.g., protection of hospital personnel or schoolmates). Mass immunization of school children has been used when epidemics have been school centered. Available data are not sufficient to recommend HAV vaccine alone for postexposure prophylaxis.

HEPATITIS B

Etiology.

HBV is a 42-nm-diameter member of the Hepadnaviridae family, a noncytopathogenic, hepatotropic group of DNA viruses. HBV has a circular, partially double-stranded DNA genome composed of approximately 3,200 nucleotides. Four genes have been identified, the S (surface), C (core), X, and P (polymer) genes. The surface of the virus includes two particles designated **hepatitis B surface antigen (HBsAg)**: a 22-nm-diameter spherical particle and a 22-nm-wide tubular particle with a variable length of up to 200?nm. The inner portion of the virion contains **hepatitis B core antigen (HBcAg)**, the nucleocapsid that encodes the viral DNA, and a nonstructural antigen called **hepatitis B e antigen (HBeAg)**, a nonparticulate soluble antigen derived from HBcAg by proteolytic self-cleavage. HBeAg serves as a marker of active viral replication. Replication of HBV occurs predominantly in the liver but also occurs in the lymphocytes, spleen, kidney, and pancreas.

Epidemiology.

Worldwide, the areas of highest prevalence of HBV infection are sub-Saharan Africa, China, parts of the Middle East, the Amazon basin, and the Pacific Islands. In the United States, the Eskimo population in Alaska has the highest prevalence rate. An estimated 6 million persons in the United States are infected, with approximately 300,000 new cases of HBV occurring each year with the highest incidence among adults ages 20–39 yr. The number of new cases in children reported each year is thought to be low but is difficult to estimate because the majority of infections in children are asymptomatic. The risk of chronic infection is related inversely to age; although less than 10% of infections occur in children, these infections account for 20–30% of all chronic cases.

The most important risk factor for acquisition of HBV in children is perinatal exposure to an HBsAg-positive mother. The risk of transmission is greatest if the mother also is HBeAg positive; 70–90% of their infants become chronically infected if untreated. During the neonatal period, hepatitis B antigen is present in blood of 2.5% of infants born to affected mothers, indicating that intrauterine infection occurred. In most cases, antigenemia appears later, suggesting that transmission occurred at the time of delivery; virus contained in amniotic fluid or in maternal feces or blood may be the source. Although most infants born to infected mothers become antigenemic by 2–5 mo of age, some infants of HBsAg-positive mothers are not affected until later ages. Of the 22,000 infants born each year to HBsAg-positive mothers in the United States, more than 98% receive immunoprophylaxis and are protected from infection.

HBsAg has been demonstrated inconsistently in human milk of infected mothers. Breast-feeding of unimmunized infants by infected mothers does not appear to confer a greater risk of hepatitis on offspring than does formula feeding, despite the possibility that cracked nipples may result in ingestion of contaminated maternal blood by a nursing infant. Routine immunoprophylaxis of infants born to HBsAg-positive mothers with HB vaccine and HBIG may eliminate theoretical risks.

Other important risk factors for HBV infection in children and adolescents include intravenous acquisition by drugs or blood products, sexual contact, institutional care, and contact with carriers. No risk factors are identified in about 40% of cases.

The risk of developing chronic HBV infection, defined as being positive for HBsAg for more than 6 mo or being negative for IgM anti-HBc and positive for HBsAg, is related inversely to age; the older the age of acquisition, the lower the risk of chronic disease. Chronic infection is associated with chronic liver disease and primary hepatocellular carcinoma, which is the most important cause of cancer-related death in Asia.

HBV is present in high concentrations in blood, serum, and serous exudates and in moderate concentrations in saliva, vaginal fluid, and semen. For these reasons, efficient transmission occurs through blood exposure and sexual contact. The incubation period ranges from 45 to 160 days, with a mean of about 120 days.

Pathogenesis.

The acute response of the liver to HBV is the same as for all hepatotropic viruses. Persistence of histologic changes in patients with hepatitis B, C, or D indicates development of chronic liver disease (Chapter 343).

HBV, unlike the other hepatotropic viruses, is a noncytopathogenic virus that causes injury by immune-mediated processes. The severity of hepatocyte injury reflects the degree of the immune response, with the most complete immune response being associated with the greatest likelihood of viral clearance and the most severe injury to hepatocytes. The first step in the process of acute hepatitis is infection of hepatocytes by HBV, resulting in viral antigens on the cell surface. The most important of these viral antigens may be the nucleocapsid antigens, HBcAg and HBeAg. These antigens, in combination with class I major histocompatibility (MHC) proteins, make the cell a target for cytotoxic T-cell lysis.

The mechanism for development of chronic hepatitis is less well understood. To permit hepatocytes to continue to be infected, the core protein or MHC class I protein may not be recognized, the cytotoxic lymphocytes may not be activated, or some other yet unknown mechanism may interfere with destruction of hepatocytes. For cell-to-cell infection to continue, some virus-containing hepatocytes must remain alive.

Immune-mediated mechanisms also are involved in the extrahepatic conditions that can be associated with HBV infections. Circulating immune complexes containing HBsAg can occur in patients who develop associated polyarteritis nodosa, membranous or membranoproliferative glomerulonephritis, polymyalgia rheumatica, leukocytoclastic vasculitis, and Guillain-Barré syndrome.

Mutations of HBV are more common than for the usual DNA viruses, and a series of mutant strains has been recognized. The most important mutation, which does not affect replication, is one that results in failure to express HBeAg and has been associated with development of severe hepatitis and perhaps more severe exacerbations of chronic HBV infection. Other core-related mutations yielding similar results have been noted.

Clinical Manifestations.

Many cases of HBV infection are asymptomatic, as evidenced by the high carriage rate of serum markers in persons who have no history of acute hepatitis. The usual acute symptomatic episode is similar to that of HAV and HCV infections but may be more severe and is more likely to include involvement of skin and joints. The first clinical evidence of HBV

---

infection is elevation of ALT levels, which begin to rise just before development of lethargy, anorexia, and malaise, which occurs about 6–7 wk after exposure. The illness may be preceded in a few children by a serum sickness–like prodrome marked by arthralgia or skin lesions, including urticarial, purpuric, macular, or maculopapular rashes. Papular acrodermatitis, the Gianotti-Crosti syndrome, also may occur. Other extrahepatic conditions associated with HBV infections in children can include polyarteritis, glomerulonephritis, and aplastic anemia. Jaundice, which may be present in about 25% of infected individuals, usually begins about 8 wk after exposure and lasts for about 4 wk. In the usual course of resolving HBV infection, symptoms are present for 6–8 wk. The percentage of children in whom clinical evidence of hepatitis develops is higher for HBV than for HAV, and the rate of fulminant hepatitis also is greater. Chronic hepatitis also occurs, and the chronic active form can result in cirrhosis and hepatocellular carcinoma, which occurs almost exclusively in patients with cirrhosis, typically 25–30 yr after HBV infection.

On physical examination, symptomatic infection results in skin and mucous membranes that are icteric, especially the sclera and the mucosa under the tongue. The liver usually is enlarged and tender to palpation. When the liver is not palpable

below the costal margin, tenderness can be demonstrated by gently striking the rib cage over the liver with a closed fist. Splenomegaly and lymphadenopathy are common.

Diagnosis.

The serologic pattern for HBV is more complex than for HAV and differs depending on whether the disease is acute, subclinical, or chronic (Fig. 339–2). Several antigens and antibodies are used to confirm the diagnosis of acute HBV infection (see Table 339–1). Routine screening for HBV infection requires assay of at least two serologic markers. HBsAg is the first serologic marker of infection to appear and is found in almost all infected persons; its rise closely coincides with the onset of symptoms. HBeAg is often present during the acute phase and indicates a highly infectious state. Because HBsAg levels fall before the end of symptoms, IgM antibody to HBcAg (IgM anti-HBcAg) also is required because it rises early after infection and persists for many months before being replaced by IgG anti-HBcAg, which persists for years. IgM anti-HBcAg usually is not present in perinatal HBV infections. Anti-HBcAg is the most valuable single serologic marker of acute HBV infection because it is present almost as early as HBsAg and continues to be present later in the course of the disease when HBsAg has disappeared. Only anti-HBsAg is present in persons immunized with

Figure 339-2 Pattern of response to hepatitis B virus infection. (HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBc = hepatitis B core antigen.)

hepatitis B vaccine, whereas anti-HBsAg and anti-HBcAg are detected in persons with resolved infection.

Treatment.

No available medical therapy is successful in the majority of persons infected with HBV. Interferon-a-2b (IFN-a2b) and lamivudine are the current therapies for treatment of chronic hepatitis B in adults older than 18 yr of age with compensated liver disease and HBV replication. IFN-a2b also has been used in children, with long-term eradication rates similar to the 25% rate reported in adults. Recombinant interferons have immunomodulatory and antiviral effects whereas lamivudine, a nucleoside analog, inhibits the viral enzyme reverse transcriptase. Persons most likely to respond have low serum HBV DNA titers, HBeAg, active inflammation, and recently acquired disease. Sustained response to treatment is not attained in most patients receiving these drugs alone or in combination. Research efforts are being focused on developing methods to stimulate a successful immune response that could result in long-term viral clearance and avoid the need for maintenance therapy. Liver transplantation also has been used to treat patients with end-stage HBV infection.

Complications.

Acute fulminant hepatitis with coagulopathy, encephalopathy, and cerebral edema occurs more frequently with HBV than with the other hepatotropic viruses, and the risk of fulminant hepatitis is further increased when there is co-infection or superinfection with HDV. Mortality due to fulminant hepatitis is more than 30%. Liver transplantation is the only effective intervention; supportive care aimed at sustaining patients while providing the time needed for regeneration of hepatic cells is the only other option.

HBV infections also can result in chronic hepatitis, which can lead to cirrhosis and primary hepatocellular carcinoma (Chapter 496). Membranous glomerulonephritis with deposition of complement and HBeAg in glomerular capillaries is a rare complication of HBV infection. Immunization to decrease the carrier rate in the population has resulted in a marked decline in the incidence of hepatocellular carcinoma in children in Taiwan.

Prevention.

Hepatitis B vaccine and hepatitis B immunoglobulin (HBIG) are available for prevention of HBV infection. Two recombinant DNA vaccines are available in the United States, and both are highly immunogenic in children. Universal immunization of all infants with hepatitis B vaccine is recommended in both pre-exposure and postexposure situations and provides long-term protection. In addition, all children who have not previously received the vaccine should be immunized by 11–12 yr of age, and catch-up programs should be implemented for unimmunized adolescents and high-risk adults. To help increase coverage, many states have made immunization a requirement for entry into junior high school. HBIG is indicated only for specific postexposure circumstances and provides only temporary protection.

Infants born to HBsAg-positive women should receive vaccine at birth, 1–2 mo, and 6 mo of age (see Table 282–4). The first dose should be accompanied by administration of 0.5?mL of HBIG as soon after delivery as possible, because the effectiveness decreases rapidly with increased time after birth. Postvaccination testing for HBsAg and anti-HBs should be at 9–15 mo. If the result is positive for anti-HBs, the child is immune to HBV. If the result is positive for HBsAg only, the parent should be counseled and the child evaluated by a pediatric hepatologist. If the result is negative for both HBsAg and anti-HBs, a second complete hepatitis B vaccine series should be administered, followed by testing for anti-HBs to determine if subsequent doses are needed.

Infants born to HBsAg-negative women should receive the vaccine at 0–2 mo, 1–4 mo, and at 6–18 mo of age. Routine postvaccination testing of immunized infants born to HBsAg-negative women or with anti-HBs is not recommended. The

three-dose series can be completed even if the interval between doses is longer than recommended.

Recommendations for postexposure prophylaxis for prevention of hepatitis B infection depend on the conditions under which the person is exposed to HBV (Table 339–4).

HEPATITIS C

Etiology.

HCV is recognized as the cause of almost all parenterally acquired cases of what was previously known as non-A, non-B hepatitis. The virus has not been isolated but was cloned in 1988 using recombinant DNA technology. HCV is a single-stranded RNA virus, classified as a separate genus within the Flaviviridae family, with marked genetic heterogeneity. It has six major genotypes and numerous subtypes and quasi-species, which may permit it to escape host immune surveillance. Genetic variation may partially explain the differences in clinical course.

Epidemiology.

HCV infection is the most common cause of chronic liver disease in the United States and causes 8,000–10,000 deaths per year. About 4 million people in the United States are estimated to be infected with HCV. Approximately 85% of infected individuals remain persistently infected, even in the absence of biochemical evidence of liver disease. Risk factors for HCV transmission in the United States have changed dramatically over the past two decades. Previously, blood transfusion was the most common route of infection but with the current screening practices, the risk of HCV is now about 0.001% per unit transfused. Illegal drug use with exposure to blood or blood products from HCV-infected persons now accounts for more than half of the cases in the United States. Sexual transmission, especially through multiple sexual partners, is the second most common cause of infection but the rate of transmission between long-term steady partners is very low. Other risk factors include imprisonment, and occupational exposure. Approximately 10% of new infections are unexplained. Perinatal transmission has been described but is uncommon except when the mother is HIV infected or has a high titer of HCV RNA. Genotypes may also be risk factors for outcome because patients with genotype 2 or 3 respond better to ribavirin or interferon therapy than those with genotype 1. Type 1b is the most common genotype in the United States. The incubation period is 7–9 wk (range of 2–24 wk).

Pathogenesis.

The pattern of acute hepatic injury is similar to that of the other hepatotropic viruses. In chronic cases, lymphoid aggregates or follicles in portal tracts are found, either alone or as part of a general inflammatory infiltration of the

TABLE 339-4 -- **Indications and Dosing Schedule for Hepatitis B Vaccine and Hepatitis B Immune Globulin**

	Vaccine			HBIG	
Groups	***Recombivax HB (µg)***	***Engerix-B (µg)***	***Schedule***	***Dose (µL)***	***Schedule***
Neonates

tracts. HCV appears to cause injury primarily by cytopathic mechanisms, but immune-mediated injury also may occur. The cytopathic component appears to be mild, because the acute illness is typically the least severe of all hepatotropic virus infections except HGV.

Clinical Manifestations.

The clinical pattern of the acute infection is similar to that of the other hepatitis viruses. Acute disease tends to be mild and insidious in onset in adults and children. Fulminant liver failure rarely occurs. HCV is the most likely hepatotropic virus to cause chronic infection; about 85% of cases become chronic, with a fluctuating pattern of elevated hepatic transaminases. After approximately 20–30 yr, about 25%

ultimately progress to cirrhosis, liver failure, and occasionally primary hepatocellular carcinoma. The clinical disease in children appears to be milder with a slower progression to cirrhosis than in adults. However, cirrhosis for HCV has been reported in children. Hepatocellular carcinoma associated with HCV, which is less effective than HBV in causing primary hepatocellular carcinoma, almost always occurs in the presence of cirrhosis and probably results from chronic inflammation and necrosis rather than an oncogenic effect of the virus.

Chronic HCV infection may be associated with small vessel vasculitis and is a common cause of essential mixed cryoglobulinemia. Other extrahepatic manifestations include cutaneous vasculitis, peripheral neuropathy, cerebritis, membranoproliferative glomerulonephritis, and nephrotic syndrome. The complications of chronic HCV infection have become one of the most common causes of liver transplantation in adults.

Diagnosis.

The clinically available assays for detection of HCV infection are based on detection of antibodies to HCV antigens or testing directly for viral RNA or DNA. These are diagnostic tests and neither the serologic nor the virologic tests can predict the severity of liver disease. The most widely used tests are the three generations of enzyme immunoassays (EIAs) that have increasing sensitivity. The predictive value of these assays is greatest in high-risk populations but the false-positive rate can be as high as 50–60% in low-risk populations. False-negative results also occur because antibodies remain negative for as long as 1–3 mo after clinical onset of illness. Anti-HCV antibody is not a protective antibody, does not confer immunity, and is usually present simultaneously with the virus. The other serologic test is the high sensitivity recombinant immunoblot assay (RIBA) which is used primarily to confirm a positive EIA result in a low-risk patient.

The virologic assays for HCV are the polymerase chain reaction (PCR) and the branched-chain DNA (bDNA test), which permit detection of small amounts of HCV RNA in serum and tissue samples within days of infection. The qualitative PCR detection is especially useful in patients with recent or perinatal infection, hypogammaglobulinemia, or immunosuppression and is very sensitive. The quantitative PCR and bDNA tests measure the viral load and are currently considered research tools but may aid in monitoring therapy in the future. Methods for determining HCV genotype are available, and can be helpful in assessing the response to therapy. The presence of HCV-associated liver disease is indicated by an elevated serum ALT level and confirmed by histologic examination of liver biopsy. Chronic HCV infection in patients with anti-HCV is defined by persistently elevated levels of ALT in the presence of hepatic fibrosis and by the presence of HCV RNA in blood. Currently there is no means to identify patients who will have progressive disease; a liver biopsy is the only means to assess the presence and extent of hepatic fibrosis. Most patients with chronic HCV hepatitis have 10^{5-7} genome copies/mL of HCV RNA in their serum.

Individuals with HCV risk factors should be screened, including persons who have used any illegal drugs (even if only once); recipients of clotting factors made before 1987 (when inactivation procedures were introduced); patients undergoing hemodialysis; persons with persistently abnormal (even slightly) ALT levels; persons who have been notified that they received blood from an HCV-positive donor; and recipients of any blood transfusion, blood component, or organ transplant before 1992. Persons with clinical hepatitis not due to hepatitis A or hepatitis B should be tested for anti-HCV. Routine screening of all pregnant women is not recommended. Children born to HCV-infected women should be tested for anti-HCV after 12 mo of age by EIA but qualitative PCR can be done in infancy. Neither national nor international adoptees are at increased risk, although adoptees should be tested if the mother was known to be at high risk.

Treatment.

Effective therapy to prevent the progression of HCV infection to cirrhosis, liver failure, or hepatocellular cancer is not yet available for the majority of patients. The Food and Drug Administration–approved monotherapy with IFN-a2b has resulted in sustained response in 10–15% of patients, defined as having normal ALT levels and negative PCR results 6 mo after completion of therapy. Combination therapy with interferon and ribavirin has yielded sustained response in about one third of patients and is now considered first-line therapy. Factors associated with improved response include mild liver histopathologic abnormalities, low serum HCV RNA levels, and infection with a genotype other than genotype 1, which is the predominant type in the United States. Preliminary experience with the use of pegylated interferon has demonstrated some improvement over IFN-a2b, but rates of sustained response are still low. Most treatment studies have been done in adults but the limited data in children have shown similar rates of success. Future treatment strategies are likely to include development of more effective protease and helicase inhibitors and drugs that can disrupt the HCV RNA genome.

Complications.

The risk of fulminant hepatitis is low with HCV, but the risk of chronic hepatitis is the highest of the hepatotropic viruses. Risk factors for progression to hepatic fibrosis include older age, male sex, and even moderate alcohol ingestion (two 1-oz drinks per day). Infected adults should refrain from using alcohol to prevent additional hepatic injury. Persons infected with HCV should be immunized with hepatitis A and hepatitis B vaccines to minimize further hepatic injury and to reduce the chance for fulminant hepatitis. The usual chronic course is a mild one even when cirrhosis develops; long-term follow-up indicates that the overall mortality of persons with transfusion-acquired HCV is no different from that of noninfected controls.

Prevention.

No vaccine is available to prevent HCV. Immunoglobulin has not proved to be of benefit. Immunoglobulin produced in the United States does not contain antibodies to HCV because blood and plasma donors are screened for anti-HCV and excluded from the donor pool.

To minimize transmission, persons with HCV should use condoms, not share

toothbrushes or razors, and not donate blood or organs.

HEPATITIS D

Etiology.

HDV, the smallest known animal virus, is considered defective because it cannot produce infection without a concurrent HBV infection. The 36-nm-diameter virus is incapable of making its own coat protein; its outer coat is composed of excess HBsAg from HBV. The inner core of the virus is single-stranded circular RNA that expresses the HDV antigen.

Epidemiology.

HDV cannot produce infection without HBV as a helper virus. HDV can cause an infection at the same time as the initial HBV infection (co-infection), or HDV can infect a person who is already infected with HBV (superinfection). Transmission usually occurs by intrafamilial or intimate contact in areas of high prevalence, which are primarily developing countries. In areas of low prevalence, such as the United States, the percutaneous route is far more common. HDV infections are uncommon in children in the United States but must be considered when fulminant hepatitis occurs. In the United States, HDV infection is found most frequently in parenteral drug abusers, the developmentally disabled, patients with hemophilia, and persons emigrating from areas that include southern Italy, parts of eastern Europe, South America, Africa, and the Middle East. HDV is uncommon in the Far East, where HBV infection is common. The incubation period for HDV superinfection is about 2–8 wk; with co-infection, the incubation period is similar to that of HBV infection.

Pathogenesis.

Liver pathology in HDV hepatitis has no distinguishing features except that damage is usually more severe. In contrast to HBV, HDV causes injury directly by cytopathic mechanisms. Many of the most severe cases of HBV infection appear to be a result of co-infection of HBV and HDV. HDV superinfection of a person who has chronic HBV infection is more common in developed countries.

Clinical Manifestations.

The symptoms of hepatitis D infection are similar to but usually more severe than those of the other hepatotropic viruses. The clinical outcome for HDV infection depends on the mechanism of infection. In co-infection, acute hepatitis, which is much more severe than for HBV alone, is common but the risk of developing chronic hepatitis is low. In superinfection, acute illness is rare and chronic hepatitis is common. However, the risk of fulminant hepatitis is highest in superinfection. Hepatitis D should be considered in any child who experiences acute hepatic failure.

Diagnosis.

HDV has not been isolated, and no circulating antigen has been identified. The diagnosis is made by detecting IgM antibody to HDV; the antibodies to HDV develop about 2–4 wk after co-infection and about 10 wk after a superinfection. A test for anti-HDV antibody is commercially available. PCR assays for viral RNA are available only as a research tool.

Complications.

HDV must be considered in all cases of fulminant hepatitis.

Prevention.

There is no vaccine for hepatitis D. However, because HDV replication cannot occur without hepatitis B co-infection, immunization against HBV also prevents HDV infection.

Hepatitis B vaccines and HBIG are used for the same indications as for hepatitis B alone.

HEPATITIS E

Etiology.

HEV has not been isolated but has been cloned using molecular techniques. This RNA virus has a nonenveloped sphere shape with spikes and is similar in structure to the caliciviruses.

Epidemiology.

Hepatitis E is the epidemic form of what was formally called non-A, non-B hepatitis. Transmission is associated with shedding of 27–34-nm particles in the stool. The highest prevalence of HEV infection has been reported in the Indian subcontinent, the Middle East, Southeast Asia, and Mexico, especially in areas with poor sanitation. In the United States, the only reported cases have been in persons who have visited or emigrated from endemic areas. The mean incubation period is about 40 days (range of 15–60 days).

Pathogenesis.

HEV appears to act as a cytopathic virus. The pathologic findings are similar to those of the other hepatitis viruses.

Clinical Manifestations.

The clinical illness associated with HEV infection is similar to HAV, the other enterically transmitted virus, but is often more severe. Both viruses produce only acute disease; chronic illness does not occur. In addition to often causing a more

severe episode than HAV, HEV affects older patients with a peak age between 15 and 34 yr. Another important clinical difference is that HEV has a high case fatality rate in pregnant women.

Diagnosis.

Recombinant DNA technology has resulted in development of antibodies to HEV particles, and IgM and IgG assays are available to distinguish between acute and resolved infections. IgM antibody to viral antigen becomes positive after about 1 wk of illness. Viral RNA can be detected in stool and serum by PCR.

Complications.

HEV is associated with a high prevalence of death in pregnant women.

Prevention.

No vaccines are available, and no evidence shows that immunoglobulin is effective in preventing HEV infections. However, immunoglobulin pooled from patients in endemic areas may prove to be effective.

HEPATITIS F

In 1994, French researchers reported the isolation of an enteric agent responsible for sporadic cases of non-A-E hepatitis and named the virus hepatitis F (HFV), for hepatitis French virus. However, their findings have not been confirmed by others and the term HFV is currently unclaimed.

HEPATITIS G

Etiology.

Hepatitis G virus (HGV), which includes HGV and GBV-C virus, was identified by PCR of the plasma of a patient with chronic hepatitis. HGV is a single-stranded RNA virus that is included in the Flaviviridae family and shares a 27% homology with HCV. The virus has not yet been isolated, but PCR testing indicates that it has a worldwide distribution and can cause chronic infection and viremia.

Epidemiology.

HGV has been reported in adults and children from all population groups, and GBV-C RNA is found in about 1.5% of blood donors and 15–20% of injection drug users in the United States. Even higher rates are found when serologic testing is used. Infection is found in many patients with HIV and has been reported in 10–20% of adults with chronic hepatitis B and hepatitis C, indicating that co-infection is a common occurrence. The primary route of spread is thought to be through transfusions, but HGV also can be transmitted by organ transplantation. Other important risk factors for infection include injection drug use, hemodialysis, and homosexual and bisexual relationships, indicating that sexual transmission also occurs. Vertical transmission also may occur.

Pathogenesis.

Most infected persons have evidence of persistent viremia, but histologic evidence of HGV infection is rare and ALT values usually are normal. To date, little evidence shows that infections with HGV cause symptomatic disease. The detection of HGV in lymphocytes suggests that the virus may behave biologically like Epstein-Barr virus or CMV. No cases of chronic hepatitis have developed in patients infected with HGV alone.

Clinical Manifestations.

HGV accounts for only a small proportion of cases of non-A-E hepatitis. Most HGV infections are not associated with hepatic inflammation, and co-infection does not seem to worsen the course of concurrent HBV or HCV infection. Because the virus is distributed so widely and is associated with only mild or no disease, it is not yet clear whether HGV is a pathogen.

Diagnosis.

The only diagnostic tests for HGV infection are PCR assays used to detect HGV RNA. Development of serologic tests will greatly improve our understanding of this virus.

Complications.

No conclusive evidence shows that HGV causes fulminant or chronic disease. Recent data indicate that patients infected with both HIV and GBV-C have a more favorable prognosis and delayed development of AIDS.

Prevention.

There is currently no method to prevent infection with HGV.

339.1 Hepatitis in Neonates

Various infectious agents have been implicated in hepatic inflammation in neonates, including bacterial and viral pathogens. Hepatitis in neonates due to specific causes usually is distinguished from the term *neonatal hepatitis*, which has been used to designate hepatic inflammation of unknown cause.

Etiology.

The six hepatotropic viruses that cause hepatitis as their primary disease manifestation rarely cause clinical hepatitis in neonates. Transplacental and perinatal transmission of HAV, HDV, and HEV is rare. The greatest risk of perinatal transmission of any hepatotropic virus occurs with HBV, but almost all neonates infected with HBV are asymptomatic. Perinatal transmission rarely is associated with

HCV, but the risk is increased in neonates of HIV-infected mothers or mothers with high titers of HCV; symptomatic infection is rare. HGV infection has been reported in neonates, but clinical illness has not been associated with infection.

Most cases of neonatal hepatitis are a result of systemic disease. Sepsis caused by systemic and extrahepatic bacterial and viral infections must always be considered when hepatitis is present in a newborn infant. Gram-negative bacterial infections are especially important causes of sepsis in newborn infants and require immediate, appropriate therapy. The pathogenesis of hepatic involvement is not understood completely, but the cholestatic effects of bacterial endotoxins appear to have an important role. Sepsis caused by gram-positive organisms and viruses can also be associated with hepatitis. In most infants, bilirubin elevation, predominantly conjugated, is of much greater magnitude than that of the aminotransferases. Syphilis also causes neonatal hepatitis.

Many other viruses, including enteroviruses, CMV, HSV, and HIV, must be considered in the etiology of neonatal hepatitis. Hepatitis associated with these viruses occurs as part of a systemic illness. Nonviral infectious causes of hepatitis in neonates include congenital syphilis and congenital toxoplasmosis.

Clinical Manifestations.

Hepatitis in neonates may be characterized by jaundice, vomiting, poor feeding, and elevated hepatic enzyme levels. When infection is caused by an organism other than one of the six hepatotropic viruses, evidence of diffuse illness usually is present and may involve the skin, central nervous, cardiorespiratory, and musculoskeletal systems. A spectrum of illness, ranging from mild to fulminant disease, can occur with any of the infecting agents listed. Fulminant hepatitis is characterized by rapid progression to very high hepatic enzyme levels, decreased production of coagulation proteins, elevated serum ammonia level, shock, coma, or death. The levels of the serum bilirubin and aminotransferase levels are poor predictors of outcome. Because of the short half-life of the coagulation proteins, the PT is the best prognostic indicator.

HBV, the most common hepatotropic virus that infects neonates, usually results in an asymptomatic infection. The most common sequence of events is for an infant to have no clinical evidence of disease and to become chronically infected and positive for HBsAg. These children often have normal or only mildly abnormal hepatic enzyme values. Liver biopsy findings may be normal initially, but chronic infection can lead to cirrhosis usually in the 3rd to 4th decades of life, greatly increasing the risk of developing primary hepatocellular carcinoma.

The differential diagnosis of hepatitis in neonates must include infectious causes, many of which are treatable, and noninfectious causes including anatomic (e.g., intrahepatic and extrahepatic biliary atresia and choledochal cyst), metabolic (e.g., cystic fibrosis, disorders of bile acid metabolism, galactosemia, tyrosinosis, and a_1 -antitrypsin deficiency), and toxic (e.g., drugs, hyperalimentation) disorders.

Treatment.

In addition to effective antimicrobial therapy for bacteria-associated hepatitis, acyclovir is effective against HSV and varicella virus, and ganciclovir and foscarnet can be used to treat CMV infections. Pleconaril is effective against enteroviruses.

Prevention.

Women should be tested for HBsAg during routine prenatal care, and infants born to women who are HBsAg positive should receive hepatitis B vaccine and HBIG (see Table 339–4) within 12?hr of birth. Additional doses of vaccine are administered 1–2 mo and 6 mo of age. Hepatitis B vaccine should be administered to all other infants, beginning in the first 2 mo of life. After administration of the first dose to infants born to HBsAg-negative mothers, the second dose should be administered at least 1 mo after the first dose, and the third dose at least 4 months after the first dose and at least 2 months after the second dose and not before 6 months of age. Routine postvaccination testing of infants to determine the presence of anti-HBs is not recommended. However, testing is advised 1–2 mo after the third vaccine dose for infants born to HBsAg-positive mothers.

Chapter 340 - Liver Abscess

Jeffrey Schwimmer
William F. Balistreri

Hepatic abscesses occur in infants in association with sepsis, umbilical vein infection, or vessel cannulation. Beyond infancy, hepatic abscesses occur most commonly in immunosuppressed patients. Of a large series of hepatic abscesses, 40% were found in patients with chronic granulomatous disease, and 20% in otherwise immunosuppressed patients (e.g., leukemia). Pyogenic hepatic abscesses may arise from the portal circulation in patients with pylephlebitis or intra-abdominal sepsis (appendicitis, inflammatory bowel disease) or generalized sepsis; cholangitis associated with biliary tract obstruction, such as by gallstones, in inflammatory bowel disease, after a Kasai procedure, and with choledochal cysts; systemic spread from an intra-abdominal infection or contiguous spread, which usually produces large abscesses; and cryptogenic biliary tract infections. Small abscesses (microabscesses) are most commonly secondary to bacteremia, candidemia, or cat-scratch disease. Implicated organisms include predominantly *Staphylococcus aureus, Escherichia coli, Salmonella,* and anaerobic organisms. Symptoms are nonspecific and may suggest systemic infection. Patients may have fever and pain in the right upper quadrant, and the liver is enlarged and may be tender to percussion. Jaundice is uncommon; serum aminotransferase and alkaline phosphatase levels may be mildly elevated. The erythrocyte sedimentation rate is high, and leukocytosis is noted. The results of blood cultures are not always positive. Roentgenographic study

of the chest may show elevation of the right hemidiaphragm with decreased mobility. Ultrasound or nuclear scans or both may indicate the site of the abscess. In most cases, treatment requires percutaneous ultrasonogram- or CT-guided needle aspiration or surgical drainage. Antibiotic therapy is based on the culture results and Gram stain of the abscess fluid. *Entamoeba histolytica* may also cause hepatic abscesses in symptomatic or asymptomatic patients with amebic infection of the gastrointestinal tract. Multiple infectious hepatic (and/or splenic) granulomas may be seen with cat scratch disease or fungi. **REFERENCES**

Chapter 341 - Liver Disease Associated with Systemic Disorders

Jeffrey Schwimmer
William F. Balistreri

Inflammatory Bowel Disease (IBD).

Hepatobiliary disease may complicate ulcerative colitis and Crohn disease (see Chapter 317). Both the manifestations and the severity vary. Fatty liver, cholangitis, drug-induced injury, chronic hepatitis, portal fibrosis, cirrhosis, hepatic abscesses, infarction, portal vein thrombosis, sclerosing cholangitis, carcinoma of the biliary tract, and cholelithiasis all have been associated with IBD. These complications are more likely to occur in patients with other extraintestinal complications, but there is no correlation with the severity of the IBD. The cause of abnormalities in liver function in patients with ulcerative colitis or Crohn disease is unknown. Total colectomy has not been beneficial in preventing or managing hepatobiliary complications in patients with ulcerative colitis.

Extensive fatty change in the liver has been found, especially in malnourished or chronically incapacitated patients with IBD. Most patients have no symptoms; hepatomegaly is the only sign. The chemical abnormalities are mild. The fatty infiltration usually subsides with therapy.

Sclerosing cholangitis may be difficult to distinguish from chronic hepatitis in patients with inflammatory bowel disease. Patients may be asymptomatic or may have jaundice, pruritus, or abdominal pain. Elevation of alkaline serum phosphatase (ALP), 5'-nucleotidase, or ?-glutamyltransferase activities is almost universal. This complication can occur any time in the course of IBD. Sclerosing cholangitis (fibrosing inflammation of various segments of the bile ducts) may lead to obliteration of the duct lumen. The clinical and biochemical picture is that of cholestasis, often with intermittent attacks of acute cholangitis (fever, jaundice, right upper quandrant pain, anorexia, weight loss, and pruritus), followed by portal hypertension. This complication occurs in 1–3% of patients with ulcerative colitis and Crohn disease.

Primary sclerosing cholangitis (not associated with inflammatory bowel disease) is uncommon in children. Cholangiography reveals beading and irregularity of the intrahepatic and extrahepatic bile ducts. Treatment is aimed at improving biliary drainage and attempting to halt progression of the obliterative process. Symptomatic treatment is required for such complications as pruritus, malnutrition, and infection. There is no definitive treatment. Ursodeoxycholic acid, in a dose of 15?mg/kg/ 24?hr, may lead to amelioration of pruritus and a decrease in abnormal biochemical values. Oral vancomycin may also improve serum ALT and GGT. The course is usually slowly progressive to a fatal outcome if liver transplantation is not carried out.

Bacterial Sepsis.

(See Chapter 98 and Chapter 163 .) Sepsis may be complicated by liver disease. The most frequently associated organisms are *Escherichia coli, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa.* It is postulated that bacterial endotoxin directly inhibits bile formation by altering the structure or function of bile canalicular membrane. Clinical manifestations may be subtle and difficult to differentiate from other causes of cholestasis. The serum bilirubin level is elevated, usually predominantly in the conjugated fraction. Serum ALP and aminotransferase activities may be elevated. Liver biopsy shows intrahepatic cholestasis with little or no hepatocyte necrosis. Kupffer cell hyperplasia and an increase in inflammatory cells are also common. Similar findings may occur with urosepsis.

Cardiac Disease.

Hepatic congestion and injury may occur as a complication of severe *chronic* or *acute congestive heart failure* (Chapter 434) or *cyanotic heart disease* (Chapter 422 , Chapter 423 , and Chapter 424). Hepatic dysfunction derives from hypoxemia, systemic venous congestion, and low cardiac output. Hepatic manifestations of left-and right-sided heart failure are similar. With decreased cardiac output, there is decreased hepatic blood flow and centrizonal hypoxia. Hepatic necrosis leads to lactic acidosis, elevated aminotransferase activities, jaundice, prolonged partial thromboplastin time, and possibly hypoglycemia. With right-sided heart failure, increases in right atrial and hepatic venous pressures lead to centrizonal sinusoidal distention that presents a barrier to oxygen diffusion. Hemorrhage, pressure atrophy, and necrosis follow. Jaundice and tender hepatomegaly occur. Ascites may also occur with chronic right-sided congestive heart failure. In patients with shock liver, elevated aminotransferase activities may return rapidly to normal when perfusion and cardiac function improve. A syndrome of acute liver failure may occur, particularly in patients with aortic coarctation. Hepatic necrosis may be found in patients with hypoplastic left-sided heart syndrome.

Hemoglobinopathies.

Patients with *sickle cell anemia* (Chapter 454.1) or *sickle cell thalassemia* (Chapter 454.1) may have hepatic dysfunction owing to acute or chronic virus-associated hepatitis, iron overload, hepatic crises related to severe intrahepatic cholestasis, sequestration, and ischemic necrosis. In addition, cholelithiasis and a benign form of extreme hyperbilirubinemia have been noted. Hepatic sickle cell crisis or “sickle hepatopathy” may produce intense right upper quadrant pain, fever, leukocytosis, right upper quadrant tenderness, and jaundice. Bilirubin levels may be markedly elevated; serum ALP levels may be only moderately elevated.

On occasion, children with sickle cell disease experience bilirubin levels exceeding

20?mg/dL; these levels are unaccompanied by severe pain or fever. There is no change in hematocrit or reticulocyte count nor any association with a hemolytic crisis. The clinical course is benign.

Cholestasis Associated with Total Parenteral Nutrition.

The most common metabolic complication of *total parenteral nutrition* (TPN) in premature infants is the development of various degrees of liver dysfunction. Cholestasis is the most severe form and is potentially fatal. It is the major factor limiting effective long-term use of TPN (Chapter 91.3).

In *low birthweight infants,* the incidence of TPN-associated cholestasis is inversely correlated with birthweight. It develops with TPN in almost half of infants with birthweights less than 1,000?g, in 20% of those 1,000–1,500?g, and in 5–10% of those 1,500–2,000?g. The incidence of cholestasis also correlates with the duration of TPN, with onset usually after 2 wk. Respiratory distress, acidosis, hypoxia, necrotizing enterocolitis,

short-bowel syndrome, and sepsis enhance the likelihood and severity of cholestasis. Associated illness, the exclusion of enteral intake, and the nature of the underlying disorder that necessitates TPN may also affect the incidence.

The onset is usually insidious, with progressive jaundice and hepatic enlargement or splenomegaly. In low birthweight infants, the onset of jaundice may overlap the phase of physiologic unconjugated hyperbilirubinemia. Any icteric infant who has received TPN for more than 1 wk should have all bilirubin determinations fractionated. Cholestasis is frequently first detected through routine monitoring of infants receiving TPN. A slow progression of abnormalities is found in biochemical measurements of hepatic function. Serum bile acid concentrations may increase. Rises in serum aminotransferase activities may be a late finding. An elevation in serum ALP activity may be due to rickets, a common complication of TPN in low birthweight infants.

In addition to cholestasis, biliary complications of intravenous nutrition include cholelithiasis and the development of biliary sludge, associated with thick, inspissated gallbladder contents. These may be asymptomatic.

An effort must be made to differentiate TPN-associated hepatic dysfunction from benign causes of hepatomegaly, such as the deposition of glycogen or fat, which is common with TPN. Serum bilirubin and bile acid levels remain within the normal range in the latter situation. Consideration of other causes of cholestasis is also appropriate. The group in which TPN-associated cholestasis most frequently occurs (i.e., infants in a neonatal intensive care unit) often receives blood products or drugs. Therefore, hepatic disease related to drug-induced liver disease is a consideration.

The most striking histologic finding in TPN-associated liver disease is canalicular cholestasis, which may begin after less than 2 wk of TPN. Bile duct proliferation may resemble that seen in patients with biliary atresia. Portal fibrosis is a late finding. Progression of injury to cirrhosis is possible. Milder changes may be reversible with discontinuation of TPN and initiation of oral feedings.

The pathogenesis of TPN-associated cholestasis is most likely multifactorial. Affected infants are of low birthweight, are receiving nothing by mouth, may have significant gastrointestinal disease, and often have other systemic complications. The administered nutrient solution has potential toxicity and may induce specific deficiencies. The omission of oral feedings and the absence of intraluminal nutrients blunt the output of the gastrointestinal hormones, which are normal stimulants to bile flow and to development of the hepatobiliary system. Potential hepatotoxins include bacterial endotoxins, specific amino acids or metabolic or degradation products, aluminum, copper, or manganese; the last two are particularly hepatotoxic.

The goal in treatment of infants with TPN-associated cholestasis is to avoid progressive liver injury. The administration of oral feedings will produce gradual resolution of the liver disease. Initiation of oral feedings of small volume or infusion of nutrients by continuous nasogastric drip may enhance biliary flow and intestinal motility while reducing bacterial translocation. This effect may occur even when the enteral intake does not provide the total caloric needs. Improved solutions that meet the specific needs of neonates may prevent deficiencies and avoid toxicities. In the decision to continue TPN, one must weigh the risk of further hepatic injury against the risk of malnutrition.

In *older children,* TPN-associated cholestasis is less common and less severe than in infants. Hepatic steatosis without cholestasis is often the only abnormality. However, biochemical abnormalities are not uncommon in older patients who are maintained on TPN for prolonged periods, either at home or in the hospital. Patients with chronic intestinal disease, which may be complicated by infection or bacterial overgrowth, are particularly susceptible to hepatic dysfunction. In most such patients, partial enteral alimentation reverses the abnormalities. It may be necessary at any age, when serum ALP or aminotransferase levels are elevated, to evaluate the underlying liver disease by liver biopsy.

Bone Marrow Transplantation.

Hepatic dysfunction is common in patients who have undergone *bone marrow transplantation.* The genesis is multifactorial and may be related to: (1) infections (viral, bacterial, or fungal), drugs, parenteral nutrition, chemotherapy, or radiation; (2) veno-occlusive disease (VOD); or (3) graft versus host disease (GVHD); or any combination of these. Candidates for bone marrow transplantation have often had pre-existing liver disease, such as viral hepatitis, drug-related injury, or malignant infiltration. Percutaneous liver biopsy in such patients may show extensive bile duct injury in GVHD, viral inclusions in cytomegalovirus disease, or the characteristic endothelial lesion in VOD; the histologic distinction is often unclear. This presents a dilemma because treatment of one suspected complication (e.g., initiation of immunosuppressive therapy for GVHD) may have a deleterious effect if the symptoms are due to another (e.g., fungal or viral infection).

VOD of the liver usually has its onset 1–3 wk after bone marrow transplantation but may appear up to 6 wk afterward. The most characteristic presentation is onset of rapid weight gain, with ascites, hepatomegaly, right upper quadrant pain, jaundice,

and oliguria. Hepatic encephalopathy and fulminant hepatic failure may follow. Less severe forms may be characterized by jaundice and ascites with a slow resolution; a mild form of VOD has histologic changes as the sole manifestation. The diagnosis rests on the exclusion of other diseases, such as congestive cardiomyopathy, constrictive pericarditis, and venous thrombosis (Budd-Chiari syndrome).

Pathologic changes in patients with VOD are best demonstrated using special (trichrome) stains to highlight the central veins. An early lesion is concentric narrowing of the lumina of small central veins, owing to edema in the subendothelial zone. There is a dense, wavy continuous band of collagen in the central veins and centrilobular hemorrhagic necrosis. The lesions may be patchy. The venular changes may progress to complete obliteration. The cause of VOD following bone marrow transplantation is not clear; it may be related to radiation, antineoplastic drugs, or both. Risk factors for VOD include high-dose conditioning regimens, leukemia, advanced age, and pre-existing liver disease.

Budd-Chiari syndrome involves occlusion of the inferior vena cava or hepatic veins and tributaries; it may be caused by obstruction resulting from a web, mass, or thrombus. The disease has rarely been noted in children. Risk factors include trauma, coagulopathies, sickle cell anemia, leukemia, polycythemia vera, hepatic abscesses, irradiation, and GVHD. The syndrome is to be regarded as distinct from VOD, which affects the centrilobular and sublobular hepatic veins, sparing the larger veins; it is not associated with thrombosis.

GVHD of the liver may be acute or chronic and is generally concomitant with GVHD in other target organs (Chapter 127). Cholestasis and hepatic injury of various degrees occur; there may be hepatic tenderness, dark urine, acholic stools, itching, and anorexia. There are parallel rises in the serum bilirubin level and the ALP activity; aspartate aminotransaminase elevation is less striking. GVHD is characterized histologically by degeneration and loss of small bile ducts and sparse inflammation, along with cholestasis.

Collagen Vascular Disease.

Hepatic involvement in patients with *collagen vascular disease* is uncommon. It has been noted especially in patients with systemic lupus erythematosus. Reactive hepatitis, chronic hepatitis, steatosis, and hepatic infarction have also been described. The association of hepatic injury with drug therapy, such as salicylate use, must be differentiated.

Obesity.

Nonalcoholic steatohepatitis (NASH) is a chronic condition of the liver, seen in obese patients, characterized by fatty infiltration, inflammation and fibrosis in an individual with little or no exposure to ethanol. See Chapter 338 .

Chapter 342 - Reye Syndrome and the Mitochondrial Hepatopathies

Jeffrey A. Rudolph
William F. Balistreri

Reye syndrome is characterized by acute encephalopathy and fatty degeneration of the liver. Investigation of this syndrome has uncovered a wide variety of previously undefined metabolic diseases whose clinical picture is similar and need to be considered in the differential diagnosis (Box 342–1). The pathophysiology involves generalized loss of mitochondrial function, leading to disturbances in fatty acid and carnitine metabolism. There is an entire class of mitochondrial hepatopathies—inherited disorders that are characterized by defects in fatty acid oxidation, oxidative phosphorylation, and general mitochondrial dysfunction.

Box 342-1. Diseases That Present a Clinical/Pathologic Picture Resembling Reye Syndrome

Metabolic disease

- Organic acidurias
- Disorders of oxidative phosphorylation
- Urea cycle defects (carbamoyl phosphate synthetase, ornithine transcarbamylase)
- Defects in fatty acid oxidation metabolism
- Acyl-CoA dehydrogenase deficiencies
- Systemic carnitine deficiency
- Hepatic carnitine palmitoyltransferase deficiency
- 3-OH, 3-methylglutaryl-CoA lyase deficiency
- Fructosemia

Central nervous system infections or intoxications (meningitis, encephalitis, toxic encephalopathy)

Hemorrhagic shock with encephalopathy

Drug or toxin ingestion (salicylate, valproate)

CoA = coenzyme A.

"CLASSIC" REYE SYNDROME

Epidemiology.

Case reports of Reye syndrome were sporadic until 1974, when almost 400 cases were reported in the United States, with a mortality rate of more than 40%. The incidence was increased in direct temporal and geographic relationship to viral epidemics, especially those caused by influenza B and varicella. By 1988, the incidence had declined dramatically; only 20 cases were reported; today this disorder is rare.

Reye syndrome presented most commonly at approximately 6 yr of age, with most cases in the 4–12-yr age range. There was no gender difference in incidence, but rural and suburban populations appeared to be more frequently affected than urban populations. It is very likely that mild cases were missed and that patients recovered without event. In the late 1970s, Reye syndrome was the most common potentially lethal virus-associated encephalopathy in the United States.

Clinical Manifestations.

Classic Reye syndrome exhibits a stereotypic, biphasic course. It usually occurs in a previously healthy child. A prodromal febrile illness, an upper respiratory tract infection (in 90% of the cases), or chickenpox (in 5–7%) is followed by an interval in which the child has seemingly recovered. The abrupt onset of protracted vomiting then occurs, usually within 5–7 days after the onset of the viral illness. Delirium, combative behavior, and stupor may occur simultaneously or within a few hours after the onset of vomiting. Neurologic symptoms may rapidly progress to seizures, coma, and death; focal neurologic signs are absent. The clinical features are best reflected in the system of clinical staging that has been proposed (Box 342–2); grades I through III represent mild to moderate illness and grades IV and V represent severe illness. The majority of affected children have mild illness without

Box 342-2. Clinical Staging of Reye Syndrome

SYMPTOMS AT TIME OF ADMISSION

I. Usually quiet, **lethargic** and sleepy, vomiting, laboratory evidence of liver dysfunction
II. Deep lethargy, **confusion**, delirium, combative, hyperventilation, hyper-reflexic
III. Obtunded, **light coma** ± seizures, decorticate rigidity, intact pupillary light reaction
IV. Seizures, deepening coma, **decerebrate rigidity**, loss of oculocephalic reflexes, fixed pupils
V. Coma, loss of deep tendon reflexes, respiratory arrest, fixed dilated pupils, **flaccidity/decerebrate** (intermittent); isoelectric electroencephalogram

progression. There is a slight to moderate liver enlargement with abnormalities of hepatic function; patients remain anicteric. Cerebrospinal fluid (CSF) is normal except for elevated pressure.

Diagnosis.

There is explosive release from liver and muscle of such enzymes as aminotransferases, creatine kinase, and lactic dehydrogenase. The activity of the mitochondrial enzyme serum glutamate dehydrogenase is greatly increased. Patients who are not in coma but who have a threefold or higher elevation in serum ammonia level are more likely to progress to coma, as are patients who have hypoprothrombinemia unresponsive to vitamin K. Younger patients may have hypoglycemia; however, these patients should be carefully screened for the presence of metabolic disease (see Box 342–1).

Pathology.

The striking and characteristic gross pathologic feature of Reye syndrome is a yellow to white liver, reflective of a high content of triglyceride. Light microscopy shows a uniform foaminess of liver cell cytoplasm with microvesicular fatty accumulation, which may be concealed in routine preparations. Electron microscopic changes include a unique alteration of mitochondrial morphology. At present, biopsy should be carried out to rule out metabolic or toxic liver disease, especially in patients younger than 1–2 yr. Histologic examination of brain tissue reveals a similar pattern of injury; grossly, marked edema is noted.

Pathogenesis.

The major site of injury is the mitochondria. The activities of hepatic intramitochondrial enzymes, including ornithine transcarbamylase (OTC), carbamoylphosphate synthetase (CPS), and pyruvate dehydrogenase, are reduced, often to less than half of their normal values. Hyperammonemia may result from acquired decreases in the activities of OTC and CPS.

The reasons for mitochondrial dysfunction are unknown. No toxic factor has yet been conclusively identified, but studies have suggested an etiologic link among Reye syndrome; the use of aspirin and/or anti-emetics, and viral infections. **It is prudent to avoid the use of aspirin as an antipyretic in pediatric patients with influenza or varicella.**

Treatment.

Successful management of Reye syndrome requires precise diagnostic evaluation to preclude disorders resembling Reye syndrome; those disorders, which are more likely to be encountered, include defects in fatty acid oxidation, oxidative phosphorylation, and other metabolic injuries presenting as acute liver failure (see Box 342–1). Control of increased intracranial pressure (ICP) secondary to cerebral edema is also imperative since this is the major lethal factor.

Early diagnosis may be aided by a high level of clinical suspicion and by assessment of hepatic function in suspected cases. Marked elevation of serum aminotransferase levels, prolongation of prothrombin time, and elevation of the serum ammonia level suggest the diagnosis. It is imperative that cerebral edema is identified and counteracted and that aerobic metabolism is maintained.

Management varies with the severity of the illness. Whereas observation alone may suffice in patients with grade I severity, more aggressive therapy is needed in patients with more severe neurologic deterioration. All patients should initially receive glucose (10–15%) intravenously, because glycogen depletion is common. In patients with cerebral edema, the amount of fluid administered should be restricted to approximately 1500?mL/m^2 day. Hyperthermia should be avoided. Coagulopathy is managed with vitamin K, fresh frozen plasma, and platelet transfusions.

In more severely ill, comatose patients, endotracheal intubation permits adequate oxygenation; hyperventilation induces hypocarbia, which decreases cerebral blood flow by cerebral vasoconstriction. Close monitoring of ICP assists in decisions about management. Stimulation of patients should be minimized because procedures such as suctioning may generate increases in ICP.

An indwelling arterial catheter permits continuous assessment of cerebral perfusion pressure. The ICP should be held to less than 20?mm Hg and the cerebral perfusion pressure to greater than 50?mm Hg. Pressure (CSF) monitoring provides an effective guide to therapy. Pentobarbital (2.5?mg/kg) to maintain a serum barbiturate level of 20–30?µg/mL may have a protective effect on the central nervous system by decreasing cerebral metabolic demands, decreasing cerebral blood flow, and causing cerebral vasoconstriction. Excessive pentobarbital may reduce cardiac function, lowering blood pressure and, therefore, cerebral perfusion pressure. Orthotopic liver transplantation is not indicated due to the reversible nature of the liver pathology.

Prognosis.

The duration of disordered cerebral function during the acute stage of illness is the best predictor of eventual outcome. In patients with grade I disease, recovery is rapid and complete. In patients with more severe disease there may be subsequent subtle neuropsychologic defects noted (in intelligence, school achievement, visuomotor integration, and concept formation).

THE MITOCHONDRIAL HEPATOPATHIES

With the advances in the identification and diagnosis of specific enzyme defects in complex metabolic disease, there has been increasing recognition that functional alterations in the mitochondria, organelles responsible for the production of cellular energy, can lead to disease. The hepatocytes, rich in mitochondria due to the energy required for the process of metabolism, are a target organ for this type of disease. The mitochondrial hepatopathies can be roughly divided into three categories: disorders of fatty acid oxidation (see Chapter 75), disorders of oxidative

phosphorylation, and the mitochondrial depletion syndromes.

Disorders of Oxidative Phosphorylation

Oxidative phosphorylation (OXPHOS) includes the oxidation of fuel molecules by oxygen and the concomitant energy transduction into adenosine triphosphate. During the oxidation process, reducing equivalents are transferred from respiratory substrates to oxygen with the resultant production of ATP via five multienzyme complexes: reduced nicotinamide-adenine dinucleotide (NAD) coenzyme Q reductase *(complex I),* coenzyme Q succinate dehydrogenase *(complex II),* coenzyme Q H_2 -cytochrome c reductase *(complex III),* cytochrome c oxidase *(complex IV),* and ATP synthetase *(complex V).* Genetic defects of the OXPHOS pathway have been described in isolation or combination with complexes I, III, IV, and V. For example, Pearson's marrow-pancreas syndrome, a disease characterized by a variable pancytopenia, pancreatic fibrosis, and hepatic steatosis and cirrhosis, has been ascribed to large deletions in complex I. Because mitochondria are maternally inherited and affected mitochondria co-segregate with normal mitochondria asymmetrically (heteroplasmy), presentation of an OXPHOS defect can occur in a single organ such as the liver or in combination with other organs. In addition, the disorders can present at any age. Most often, they are a cause of rapidly fatal hepatic failure in neonates. Children affected later in life usually present with hepatomegaly and jaundice, and often with neurologic involvement. While mitochondrial DNA defects have been the most common mutations described in OXPHOS disease, nuclear DNA mutations have also been implicated as the OXPHOS complexes are derived from both nuclear and mitochondrial gene products. A complex III deficiency is secondary to a defect in the nuclear DNA gene BCS1L and presents as a tubulopathy, encephalopathy, and liver failure. Diagnosis of OXPHOS mutation relies on enzymatic analysis or tests of mitochondrial respiration performed on fresh or fresh frozen liver samples, available at a very

limited number of locations. Therapy is limited to supportive care. Liver transplantation has been suggested when involvement is solely limited to the hepatocytes.

Mitochondrial Depletion Syndromes

A rare disorder that presents with neonatal jaundice and liver failure has been ascribed to very low levels of mitochondrial DNA in hepatocytes. This disorder, termed the *mitochondrial DNA depletion syndrome* (MDS), is a recognized cause of isolated liver disease in the newborn period. These infants present within the first few weeks of life with lactic acidosis, conjugated hyperbilirubinemia, and generalized metabolic dysfunction. The number of mitochondria per hepatocyte is normal or even increased, but there are very low levels of mitochondrial DNA (<10%) leading to depressed activity of OXPHOS. Navajo neurohepatopathy, an autosomal recessive disease described exclusively in full-blooded Navajo Indians, is also characterized as depletion of mitochondrial DNA, suggesting a similar pathogenesis. Diagnosis is based on ultrastructural changes on liver biopsy, including changes in mitochondrial number, size, and cristae appearance, and the quantification of mitochondrial DNA copy number. Therapy is limited to supportive care; transplantation has been proposed for isolated liver disease.

Chapter 343 - Autoimmune (Chronic) Hepatitis

Benjamin L. Shneider
Frederick J. Suchy

Autoimmune hepatitis is a chronic hepatic inflammatory process manifested by elevated serum aminotransaminase concentrations and liver-associated serum autoantibodies and hypergammaglobulinemia. The target of the inflammatory process can include both hepatocytes and bile duct epithelium. Chronicity is determined either by duration of liver disease (typically more than 3 to 6 mo) or evidence of either severe liver disease or physical stigmata of chronic liver disease (clubbing, spider telangiectasia, hepatosplenomegaly). The severity is variable; the affected child may have only biochemical evidence of liver dysfunction, may have stigmata of chronic liver disease, or may present in hepatic failure.

Chronic hepatitis can also be caused by persistent viral infection, drugs, metabolic diseases, or unknown factors (Box 343–1). Approximately 15–20% of cases are associated with hepatitis B infection (Chapter 339); unusually severe disease may be caused by superimposed infection with hepatitis D (a defective RNA virus that is dependent on replicating hepatitis B virus). Over 90% of hepatitis B infections in the 1st yr of life become chronic compared with 5–10% among older children and adults. Chronic hepatitis develops in over 50% of acute hepatitis C virus infections. Patients receiving blood products or who have had massive transfusions are at increased risk. Hepatitis A or E viruses do not cause chronic hepatitis. Drugs commonly used in children that may cause chronic liver injury include isoniazid, methyldopa, pemoline, nitrofurantoin, dantrolene, minocycline, pemoline, and the sulfonamides. Metabolic diseases can lead to chronic hepatitis including a_1 -antitrypsin deficiency, inborn errors of bile acid biosynthesis, and Wilson disease. Steatohepatitis, usually associated with obesity, is another common cause of chronic hepatitis; it is relatively benign and responds to weight reduction and/or vitamin E therapy. Progression to cirrhosis has been described in adults. In most cases, the cause of chronic hepatitis is unknown; in many, an autoimmune mechanism is suggested by the finding of serum antinuclear and anti-smooth muscle antibodies and by multisystem involvement (arthropathy, thyroiditis, rashes, and Coombs-positive hemolytic anemia).

Histologic features help characterize chronic hepatitis. Subdivision of chronic hepatitis into a persistent vs active form on the basis of histologic findings is not as useful as once thought. The finding of inflammation contained within the limiting plate of the portal tract (chronic persistent hepatitis) and an absence of fibrosis/cirrhosis suggest a more benign course. The finding of activity on biopsy may be predictive of response to antiviral therapy if hepatitis B infection is present and is a criterion used in the diagnosis of autoimmune hepatitis. Histologic features help identify the etiology; characteristic PAS-positive, diastase-resistant granules are seen in a_1 -antitrypsin deficiency,

while macrovesicular and microvesicular neutral fat accumulation within hepatocytes is a feature of steatohepatitis. Bile duct injury may suggest an autoimmune cholangiopathy. Ultrastructural analysis may suggest distinct types of storage disorders.

Autoimmune hepatitis is a clinical constellation that suggests an immune-mediated disease process; it is responsive to immunosuppressive therapy. Autoimmune hepatitis typically refers to a primarily hepatocyte-specific process, whereas autoimmune cholangiopathy and sclerosing cholangitis are predominated by intra- and extrahepatic bile duct injury. De novo hepatitis is seen in a subset of liver transplant recipients whose initial disease was not autoimmune.

Etiology.

The cause of autoimmune hepatitis is unknown. It may be the result of an imbalance between CD4 and CD8 T-lymphocyte activity. Genetic predisposition may play an important role in the development of autoimmune hepatitis, although viral infection or drug exposure may initiate the process.

Pathology.

The histologic features common to untreated cases include (1) inflammatory infiltrates, consisting of lymphocytes and plasma cells that expand portal areas and often penetrate the lobule; (2) moderate to severe piecemeal necrosis of hepatocytes extending outward from the limiting plate; and (3) variable necrosis, fibrosis, and zones of parenchymal collapse spanning neighboring portal triads or between a portal triad and central vein (bridging necrosis); and (4) variable degrees of bile duct epithelial injury. Distortion of hepatic architecture may be severe; cirrhosis may be present in children at the time of diagnosis.

Clinical Manifestations.

The clinical features and course of autoimmune hepatitis are extremely variable. Signs and symptoms at the time of presentation include a wide spectrum of disease including a substantial number of asymptomatic patients and some who have an acute, even fulminant, onset. In 25–30% of patients with autoimmune hepatitis, particularly children, the illness may mimic acute viral hepatitis. In most, the onset is insidious. Patients may be asymptomatic or have fatigue, malaise, behavioral changes, anorexia, and amenorrhea, sometimes for many months before jaundice or stigmata of chronic liver disease are recognized. Extrahepatic manifestations may include arthritis, vasculitis, nephritis, thyroiditis, Coombs-positive anemia, and rash. Some patients' initial clinical features may reflect cirrhosis (ascites, bleeding esophageal varices, or hepatic encephalopathy).

There is usually mild to moderate jaundice. Spider telangiectasias and palmar erythema may be present. The liver is often tender and slightly enlarged but may not be felt in patients with cirrhosis. The spleen is commonly enlarged. Edema and ascites may be present in advanced cases. Evidence of involvement of other organ systems may be found.

Laboratory Findings.

The findings are related to the severity of presentation. In many asymptomatic cases, serum aminotransferase may range between 100 and 300?IU/L, whereas levels in excess of 1,000?IU/L can be seen in symptomatic young patients. Serum bilirubin concentrations (predominantly the direct reacting fraction) are commonly 2–10?mg/dL. Serum alkaline phosphatase activity is normal to slightly increased but may be more significantly elevated in autoimmune cholangiopathy. Serum ?-globulin levels may show marked polyclonal elevations. Hypoalbuminemia is common. The prothrombin time is prolonged, most often as a result of vitamin K deficiency but also as a reflection of impaired hepatocellular function. A normochromic normocytic anemia, leukopenia, and thrombocytopenia are present and become more severe with the development of portal hypertension and hypersplenism.

Most patients with autoimmune hepatitis have hypergammaglobulinemia. Serum IgG levels usually exceed 16?g/L. Characteristic patterns of serum autoantibodies define several subgroups of autoimmune hepatitis. The most common pattern is the formation of non-organ specific antibodies, such as antiactin (smooth muscle), antinuclear, and antimitochondrial antibodies. Approximately 50% of these patients are 10–20 yr of age. High titers of a liver-kidney microsomal (LKM) antibody are detected in another form that usually affects children 2–14 yr of age. A subgroup of primarily young women may demonstrate autoantibodies against a soluble liver antigen but not against nuclear or microsomal proteins. Antineutrophil cytoplasmic antibodies may be seen more commonly in autoimmune cholangiopathy. Autoantibodies are rare in healthy children so that titers as low as 1:40 should be considered significant. Up to 20% of patients with apparent autoimmune hepatitis may not have autoantibodies at presentation. Antibodies to a cytochrome P450 component of LKM are commonly found in adult patients with chronic hepatitis C infection. Homologies in antigenic peptide epitopes between the hepatitis C virus and

cytochrome P450 may explain this. Other less common autoantibodies include rheumatoid factor, anti–parietal cell antibodies, and antithyroid antibodies. A Coombs-positive hemolytic anemia may be present.

Diagnosis.

Autoimmune hepatitis is a clinical diagnosis based upon certain diagnostic criteria; no single test will make this diagnosis. Diagnostic criteria with scoring systems have been developed for adults and modified slightly for children. Important positive features include female gender, primary elevation in transaminases and not alkaline phosphatase, elevated ?-globulin levels, the presence of autoantibodies (most commonly antinuclear, smooth muscle, or liver kidney microsome), and characteristic histologic findings. Important negative features include the absence of viral markers (hepatitis B, C, D) of infection, absence of a history of drug or blood product exposure, and negligible alcohol consumption.

All other conditions that might lead to chronic hepatitis should be excluded (see Box 343–1). The differential diagnosis includes a_1 -antitrypsin deficiency (Chapter 338.6) and Wilson disease (Chapter 338.2). The former disorder must be excluded by performing a_1 -antitrypsin phenotyping and the latter by measuring serum ceruloplasmin and 24-hr urinary copper excretion and hepatic copper levels. Chronic active hepatitis may occur in patients with inflammatory bowel disease, but liver dysfunction in such patients is more commonly due to pericholangitis or sclerosing cholangitis. An ultrasonogram should be done to identify a choledochal cyst or other structural disorders of the biliary system. Dilated or obliterated veins on ultrasonography suggest the possibility of the Budd-Chiari syndrome.

Treatment.

Corticosteroid therapy, with or without low doses of azathioprine, improves the clinical, biochemical, and histologic features in most patients with autoimmune hepatitis and prolongs survival in most patients with severe disease. The choleretic agent ursodeoxycholic acid may be particularly useful in patients with biliary features of their disease.

The goal is to suppress or eliminate hepatic inflammation with minimal side effects. Prednisone at an initial dose of 1–2?mg/kg/24?hr is continued until aminotransferase values return to less than twice the upper limit of normal. The dose should then be lowered in 5-mg decrements over 4 to 6 wk until a maintenance dose of 0.2–0.3?mg/kg/24?hr is achieved. In patients who respond poorly, who experience severe side effects, or who cannot be maintained on low-dose steroids, azathioprine (1.5?mg/kg/24?hr, up to 100?mg/24?hr) may be added, with frequent monitoring for bone marrow suppression. Single-agent therapy with alternate-day corticosteroids should be used with great caution. This form of treatment may produce improvement or even normalization of serum aminotransferase activities, but histologic resolution may not occur. In patients with a mild and relatively asymptomatic presentation, some favor a lower starting

dose of prednisone (10–20?mg) coupled with the simultaneous early administration of either 6-mercaptopurine (1–1.5?mg/kg/ 24?hr) or azathioprine (1.5–2.0?mg/kg/24?hr). Anecdotal reports have shown a potential for cyclosporine and tacrolimus in the management of cases refractory to standard therapy. Use of these agents should be reserved for practitioners with extensive experience in their administration, because they have a poor therapeutic to toxic ratio.

Histologic progress does not necessarily need to be assessed by sequential liver biopsies, although biochemical remission does not ensure histologic resolution. Follow-up liver biopsy is therefore especially important in those patients where consideration is given to discontinuing corticosteroid therapy. In patients with disappearance of symptoms and biochemical abnormalities and resolution of the necroinflammatory process on biopsy, an attempt at gradual discontinuation of medication is justified. There is a high rate of relapse after discontinuation of therapy.

The therapy of chronic viral hepatitis differs from that for autoimmune disease (also see Chapter 339). Chronic hepatitis B infection is defined by persistently elevated serum levels of HBV DNA and HbsAg, with or without HbeAg. In addition, there is persistent elevated serum aminotransferases and histologic evidence of chronic hepatitis. Therapy with interferon-a (5–10?MU/m^2 body surface area subcutaneously, 3 × wk) for 4–6 mo will induce a remission (defined as conversion from HbeAG to HbeAg positivity) in 25–40%. Side effects of interferon-a include systemic flu-like episodes, behavioral and cognitive changes, development of autoantibodies, and increased susceptibility to bacterial infection. Lamivudine, an oral nucleoside analog, is a less toxic but apparently less effective therapeutic option.

Chronic hepatitis C virus is defined by the presence of HCV RNA in blood. Progression to end-stage liver disease has been seen in some children, and thus chronically elevated aminotransferases and histologic evidence of activity may be an indication for treatment. Therapy includes interferon-a (3?MU/m^2 body surface subcutaneously 3 × wk) for 6–12 mo. Long-term clearance of virus is seen in less than 25% of treated children. The combination of long-acting peginterferon alpha 2 and oral ribavirin is more effective in adult patients.

Prognosis.

The initial response to therapy in autoimmune hepatitis is generally prompt, with a greater than 75% rate of remission. Transaminases and bilirubin fall to near-normal levels often within the first 1–3 mo. When present, abnormalities in serum albumin and prothrombin time also respond over a longer period (3–9 mo). In patients meeting the criteria for tapering and then withdrawal of treatment (25 to 40% of children), 50% are weaned from all medication; in the other 50%, relapse occurs after a variable period. Relapse usually responds to retreatment. Many children will not meet the criteria for an attempt at discontinuation of immunosuppression and should be maintained on the smallest dose of prednisone that minimizes biochemical activity of the disease. A careful balance of the risks of continued immunosuppression and ongoing hepatitis must be continually evaluated. This requires continual screening for complications of medical therapy (ophthalmologic

examination, bone density measurement, blood pressure monitoring). Intermittent flares of hepatitis can occur and may necessitate recycling of prednisone therapy. Some children have a relatively steroid-resistant form of hepatitis. More extensive evaluations of the etiology of their hepatitis should be undertaken, directed particularly at reassessing for the presence of either sclerosing cholangitis or Wilson disease. Progression to cirrhosis may occur in autoimmune hepatitis despite a good response to drug therapy and prolongation of life.

Orthotopic liver transplantation has been successful in patients with end-stage liver disease associated with autoimmune hepatitis (Chapter 349). Disease may recur after transplantation. Thus, indication for transplantation should include evidence of hepatic decompensation and not resistance to standard immunosuppressive regimens.

Chapter 344 - Drug- and Toxin-Induced Liver Injury

Frederick J. Suchy

The liver is the main site of drug metabolism and is particularly susceptible to structural and functional injury after ingestion, parenteral administration, or inhalation of chemical agents, drugs, plant derivatives (home remedies), or environmental toxins. The possibility of drug use or toxin exposure at home or in the parental workplace should be explored for every child with liver dysfunction. The clinical spectrum of illness may vary from asymptomatic biochemical abnormalities of liver function to fulminant failure.

Hepatic metabolism of drugs and toxins is mediated by a sequence of enzymatic reactions that, in large part, transform hydrophobic, less excretable molecules into more nontoxic, hydrophilic compounds that can be readily excreted in urine or bile. *Phase 1* of the process involves enzymatic activation of the substrate to reactive intermediates containing a carboxyl, phenol, epoxide, or hydroxyl group. Mixed-function mono-oxygenase, cytochrome c-reductase, various hydrolases, and the cytochrome P450 system are involved in this process. Nonspecific induction of these enzymatic pathways, which commonly occurs with administration of certain drugs such as anticonvulsants, may alter the metabolism of other drugs and increase the potential for hepatotoxicity. A single agent may be metabolized by more than one biochemical reaction. The reactive intermediates that are potentially damaging to the cell are enzymatically conjugated in *phase 2* reactions with glucuronic acid, sulfate, or glutathione. Some drugs may be directly metabolized by these conjugating reactions without first undergoing *phase 1* activation. Pathways for biotransformation develop early in life, with the possible exception of enzymes for oxidizing polycyclic aromatic hydrocarbons and for forming glucuronide conjugates. Mechanisms for the uptake and excretion of organic ions may also be deficient early in life. Genetic polymorphisms in genes encoding enzymes mediating *phase 1* and

phase 2 reactions may be associated with impaired drug metabolism and an increased risk of hepatotoxicity. Some cases of idiosyncratic hepatotoxicity may occur as a result of aberrations in *phase 1* drug metabolism producing intermediates of unusual hepatotoxic potential combined with developmental, acquired, or relative inefficiency of *phase 2* conjugating reactions. Therefore, children may be more or less susceptible than adults to hepatotoxic reactions; for example, liver injury after the use of the anesthetic halothane is rare in children, and acetaminophen toxicity is unusual in infants compared with adolescents, whereas most cases of fatal hepatotoxicity associated with sodium valproate use have been reported in children. Excess or prolonged therapeutic administration of acetaminophen combined with reductions in caloric or protein intake may produce hepatotoxicity in children. It is proposed that in this setting, acetaminophen metabolism may be impaired by reduced synthesis of sulfated and glucuronated metabolites and reduced stores of glutathione. In some cases, immaturity of hepatic drug metabolic pathways may prevent degradation of a toxic agent; under other circumstances, the same immaturity might limit the formation of toxic metabolites.

Chemical hepatotoxicity may be (1) *predictable* or (2) *idiosyncratic. Predictable* hepatotoxicity implies a high incidence of hepatic injury in exposed individuals, with dose dependence. The agents involved may damage the hepatocyte directly through alteration of membrane lipids (peroxidation) or through denaturation of proteins; such agents include carbon tetrachloride and trichloroethylene. Indirect injury may occur through interference with metabolic pathways essential for cell integrity or through distortion of cellular constituents by covalent binding of a reactive metabolite; examples include the liver injury produced by acetaminophen or by antimetabolites such as methotrexate or 6-mercaptopurine.

Idiosyncratic hepatotoxicity is infrequent and unpredictable. The likelihood of injury is not dose dependent and may occur at any time during exposure to the agent. An idiosyncratic reaction may be immunologically mediated as a result of prior sensitization (hypersensitivity); extrahepatic manifestations of hypersensitivity may include fever, rash, arthralgia, and eosinophilia. Duration of exposure before reaction is generally 1–4 wk, with prompt recurrence of injury on re-exposure.

Studies indicate that arene oxides, generated through oxidative (cytochrome P450) metabolism of aromatic anticonvulsants (phenytoin, phenobarbital, carbamazepine), may initiate the pathogenesis of hypersensitivity reactions. Arene oxides, formed in vivo, may bind to cellular macromolecules, thus perturbing cell function and possibly initiating immunologic mechanisms of liver injury. Idiosyncratic drug reactions in certain patients may reflect aberrant pathways for drug metabolism, with production of toxic intermediates (isoniazid and sodium valproate may cause liver damage through this mechanism). Duration of drug use before liver injury varies (wks to 1 yr or more), and the response to re-exposure may be delayed.

The *pathologic* spectrum of drug-induced liver disease is extremely wide, is rarely specific, and may mimic other liver diseases (Table 344–1). Predictable hepatotoxins such as acetaminophen produce centrilobular necrosis of hepatocytes. Steatosis is an important feature of tetracycline (microvesicular) and ethanol (macrovesicular) toxicities. A cholestatic hepatitis can be observed with injury caused by erythromycin estolate and chlorpromazine. Cholestasis without inflammation may be a toxic effect of estrogens and anabolic steroids. Use of oral contraceptives and androgens has also been associated with benign and malignant liver tumors. Some idiosyncratic drug reactions may produce mixed patterns of injury with diffuse cholestasis and cell necrosis. Several antineoplastic drugs and some herbal remedies have produced hepatic veno-occlusive disease. Chronic hepatitis has been associated with the use of methyldopa and nitrofurantoin.

TABLE 344-1 -- **Patterns of Hepatic Drug Injury**

Disease	Drug
Centrilobular necrosis	Acetaminophen Halothane
Microvesicular steatosis	Valproic acid
Acute hepatitis	Isoniazid
General hypersensitivity	Sulfonamides Phenytoin
Fibrosis	Methotrexate
Cholestasis	Chlorpromazine Erythromycin Estrogens
Veno-occlusive disease	Irradiation plus busulfan Cyclophosphamide
Portal and hepatic vein thrombosis	Estrogens Androgens
Biliary sludge	Ceftriaxone
Hepatic adenoma or hepatocellular carcinoma	Oral contraceptives Anabolic steroids

Clinical manifestations may be mild and nonspecific, such as fever and malaise. Fever, rash, and arthralgia may be prominent in cases of hypersensitivity. In ill, hospitalized patients, the signs and symptoms of hepatic drug toxicity may be difficult to separate from the underlying illness. The differential diagnosis should include acute and chronic viral hepatitis, biliary tract disease, septicemia, ischemic and hypoxic liver injury, malignant infiltration, and inherited metabolic liver disease.

The *laboratory features* of drug- or toxin-related liver disease are extremely variable. Hepatocyte damage may lead to elevations of serum aminotransferase activities and serum bilirubin levels and to impaired synthetic function as evidenced by decreased serum coagulation factors and albumin. Hyperammonemia may occur with liver failure or with selective inhibition of the urea cycle (sodium valproate). Toxicologic screening of blood and urine specimens may aid in the detection of drug or toxin exposure. Percutaneous liver biopsy may be necessary to distinguish drug injury from complications of an underlying disorder or from intercurrent infection.

Slight elevation of serum aminotransferase activities (generally less than two to three times normal) may occur during therapy with drugs, particularly anticonvulsants, capable of inducing microsomal pathways for drug metabolism. Liver biopsy reveals proliferation of smooth endoplasmic reticulum but no significant liver injury. Liver test abnormalities often resolve with continued drug therapy.

Treatment of drug- or toxin-related liver injury is mainly supportive. Contact with the offending agent should be avoided. Corticosteroids may have a role in immune-mediated disease. *N*-acetylcysteine therapy, by stimulating glutathione synthesis, is effective in preventing hepatotoxicity when administered within 16?hr after an acute overdose of acetaminophen and appears to improve survival in patients with severe liver injury even up to 36?hr after ingestion (also see Chapter 704.2). Orthotopic liver transplantation may be required for treatment of drug- or toxin-induced hepatic failure.

The *prognosis* of drug- or toxin-induced liver injury depends on its type and severity. Injury is usually completely reversible when the hepatotoxic factor is withdrawn. The mortality of submassive hepatic necrosis with fulminant liver failure may, however, exceed 50%. With continued use of certain drugs, such as methotrexate, effects of hepatoxicity may proceed insidiously to cirrhosis. Neoplasia may follow long-term androgen therapy. Rechallenge with a drug suspected of having caused previous liver injury is rarely justified and may result in fatal hepatic necrosis.

Chapter 345 - Fulminant Hepatic Failure

Frederick J. Suchy

Fulminant hepatic failure is strictly defined as a clinical syndrome resulting from massive necrosis of hepatocytes or from severe functional impairment of hepatocytes in a patient who does not have a pre-existing liver disease. The disorder usually evolves over a period of fewer than 8 wk. Synthetic, excretory, and detoxifying functions of the liver all are severely impaired, with hepatic encephalopathy an essential diagnostic criterion. This narrow definition may be problematic in infants because liver failure in the perinatal period may be associated with prenatal liver injury and even cirrhosis. Examples include neonatal iron storage disease, tyrosinemia, and some cases of congenital viral infection. In these disorders, liver disease may be noticed at birth or after several days of apparent well-being. Fulminant Wilson disease also occurs in children who were previously asymptomatic but by definition have pre-existing liver disease. Moreover, in some cases of liver failure, particularly in so-called non-A, non-B, non-C hepatitis, the onset of encephalopathy may occur later, from 8–28 wk after the onset of jaundice.

Etiology.

Fulminant hepatic failure is most commonly a complication of viral hepatitis (A, B, D, E, possibly C, and others). An unusually high risk of fulminant hepatic failure occurs in young people who have combined infections with the hepatitis B virus (HBV) and hepatitis D. Mutations in the precore and/or promoter region of HBV DNA have been associated with fulminant and severe hepatitis. HBV is also responsible for some cases of fulminant liver failure in the absence of serologic markers of HBV infection but with HBV DNA found in the liver. Hepatitis C and E viruses are uncommon causes of fulminant hepatic failure in the United States. Patients with chronic HCV are at risk if they have superinfection with HAV. An additional, unidentified virus accounts for the majority of what in the past has been termed fulminant non-A, non-B, non-C hepatitis. This form may be the most common cause of fulminant hepatic failure in children. The disease occurs sporadically and usually without the parenteral risk factors of HBV or HCV. Epstein-Barr virus, herpes simplex virus, adenovirus, enterovirus, cytomegalovirus, parvovirus B19, and varicella-zoster infections may produce fulminant hepatitis in children. Fulminant hepatic failure may also be caused by autoimmune hepatitis.

Various hepatotoxic drugs and chemicals may also cause fulminant hepatic failure.

Predictable liver injury may occur after exposure to carbon tetrachloride and *Amanita phalloides* mushroom or after acetaminophen overdose. Idiosyncratic damage may follow the use of drugs such as halothane or sodium valproate. Ischemia and hypoxia resulting from hepatic vascular occlusion, congestive heart failure, cyanotic congenital heart disease, or circulatory shock may produce liver failure. Metabolic disorders associated with hepatic failure include Wilson disease, acute fatty liver of pregnancy, galactosemia, hereditary tyrosinemia, hereditary fructose intolerance, neonatal iron storage disease, defects in ß-oxidation of fatty acids, and deficiencies of mitochondrial electron transport.

Pathology.

Liver biopsy usually reveals patchy or confluent massive necrosis of hepatocytes. Multilobular or bridging necrosis may be associated with collapse of the reticulin framework of the liver. There may be little or no regeneration of hepatocytes. A zonal pattern of necrosis may be observed with certain insults (e.g., centrilobular damage is associated with acetaminophen hepatotoxicity or with circulatory shock). Evidence of severe hepatocyte dysfunction rather than cell necrosis may occasionally be the predominant histologic finding (e.g., microvesicular fatty infiltrate of hepatocytes is observed in Reye syndrome, ß-oxidation defects, and tetracycline toxicity).

Pathogenesis.

The mechanisms that lead to fulminant hepatic failure are poorly understood. It is unknown why only about 1–2% of patients with viral hepatitis experience liver failure. Massive destruction of hepatocytes may represent both a direct cytotoxic effect of the virus and an immune response to the viral antigens. One third to one half of patients with HBV-induced liver failure become negative for serum hepatitis B surface antigen within a few days of presentation and often have no detectable HBV antigen or HBV DNA in serum. These findings suggest a hyperimmune response to the virus that underlies the massive liver necrosis. Formation of hepatotoxic metabolites that bind covalently to macromolecular cell constituents is involved in the liver injury produced by drugs such as acetaminophen and isoniazid; fulminant hepatic failure may follow depletion of intracellular substrates involved in detoxification, particularly glutathione. Whatever the initial cause of hepatocyte injury, various factors may contribute to the pathogenesis of liver failure, including impaired hepatocyte regeneration, altered parenchymal perfusion, endotoxemia, and decreased hepatic reticuloendothelial function.

The pathogenesis of hepatic encephalopathy may relate to increased serum levels of ammonia, false neurotransmitters, amines, increased ?-aminobutyric acid receptor activity, or increased circulating levels of endogenous benzodiazepine-like compounds. Decreased hepatic clearance of these substances may produce marked central nervous system dysfunction.

Clinical Manifestations.

Fulminant hepatic failure may complicate previously known acute liver disease or be the presenting feature of liver disease. A history of developmental delay and/or neuromuscular dysfunction may indicate an underlying mitochondrial or ß oxidation defect. A child with fulminant hepatic failure has usually been previously healthy and most often has no risk factors for liver disease such as hepatitis or blood product exposure. Progressive jaundice, fetor hepaticus, fever, anorexia, vomiting, and abdominal pain are common. A rapid decrease in liver size without clinical improvement is an ominous sign. A hemorrhagic diathesis and ascites may develop. Patients should be closely observed for hepatic encephalopathy, which is initially characterized by minor disturbances of consciousness or motor function. Irritability, poor feeding, and a change in sleep rhythm may be the only findings in infants; asterixis may be demonstrable in older children. Patients are often somnolent or confused or combative on arousal and eventually may become responsive only to painful stimuli. Patients may rapidly progress to deeper stages of coma in which extensor responses and decerebrate and decorticate posturing appear. Respirations are usually increased early, but respiratory failure may occur in stage IV coma (Table 345–1).

TABLE 345-1 -- **Stages of Hepatic Encephalopathy**

	Stages			
	I	*II*	*III*	*IV*
Symptoms	Periods of lethargy, euphoria; reversal of day-night sleeping; may be alert	Drowsiness, inappropriate behavior, agitation, wide mood swings, disorientation	Stupor but arousable, confused, incoherent speech	Coma IVa responds to noxious stimuli IVb no response
Signs	Trouble drawing figures, performing mental tasks	Asterixis, fetor hepaticus, incontinence	Asterixis, hyperreflexia, extensor reflexes, rigidity	Areflexia, no asterixis, flaccidity
Electroencephalogram	Normal	Generalized slowing, ? waves	Markedly abnormal, triphasic waves	Markedly abnormal bilateral slowing, d waves, electric-cortical silence

Laboratory Findings.

Serum direct and indirect bilirubin levels and serum aminotransferase activities may be markedly elevated. However, serum aminotransferase activities do not correlate well with the severity of the illness and may actually decrease as a patient

deteriorates. The blood ammonia concentration is usually increased, but hepatic coma can occur in patients with a normal blood ammonia level. Prothrombin time is always prolonged and often does not improve after parenteral administration of vitamin K. Hypoglycemia can occur, particularly in infants. Hypokalemia, hyponatremia, metabolic acidosis, or respiratory alkalosis may develop.

Treatment.

Management of fulminant hepatic failure is supportive. No therapy is known to reverse hepatocyte injury or to promote hepatic regeneration.

An infant or child with advanced hepatic coma should be treated in an intensive care unit where continuous monitoring of vital functions is possible. Endotracheal intubation may be required to prevent aspiration, to reduce cerebral edema by hyperventilation, and to facilitate pulmonary toilet. Mechanical ventilation and supplemental oxygen are often necessary in advanced coma. Electrolyte and glucose solutions should be administered intravenously to maintain urine output, to correct or prevent hypoglycemia, and to maintain normal serum potassium concentrations. Hyponatremia is common but is usually dilutional and not a result of sodium depletion. Parenteral supplementation with calcium, phosphorus, and magnesium may be required. Coagulopathy should be treated with parenteral administration of vitamin K and may require fresh frozen plasma; disseminated intravascular coagulation may also occur. Plasmapheresis may permit temporary correction of the bleeding diathesis without resulting in volume overload. Continuous hemofiltration is useful for management of fluid overload and acute renal failure. Prophylactic use of antacids or H_2 receptor blockers or both should be considered because of the high risk of gastrointestinal bleeding. Hypovolemia should be avoided and treated with cautious infusions of fluids and blood products. Renal dysfunction may result from dehydration, acute tubular necrosis, or functional renal failure (hepatorenal syndrome). Patients should be monitored closely for infection, including sepsis, pneumonia, peritonitis, and urinary tract infections. At least 50% of patients experience serious infection. Gram-positive organisms *(Staphylococcus aureus, S. epidermidis)* are the most common pathogens, but gram-negative and fungal infections are also observed. Cerebral edema is an extremely serious complication that responds poorly to measures such as corticosteroid administration and osmotic diuresis. Monitoring intracranial pressure may be useful in preventing severe cerebral edema, in maintaining cerebral perfusion pressure, and in establishing the suitability of a patient for liver transplantation.

Gastrointestinal hemorrhage, infection, constipation, sedatives, electrolyte imbalance, and hypovolemia may precipitate encephalopathy and should be identified and corrected. Protein intake should be restricted or eliminated. The gut should be purged with several enemas. Lactulose should be given every 2–4?hr orally or by nasogastric tube in doses (10–50?mL) sufficient to cause diarrhea. The dose is then adjusted to produce several acidic, loose bowel movements daily. Lactulose syrup diluted with 1–3 volumes of water may also be given as a retention enema every 6?hr. Lactulose, a nonabsorbable disaccharide, is metabolized to organic acids by colonic bacteria; it probably lowers blood ammonia levels through decreasing microbial ammonia production and through trapping of ammonia in acidic intestinal contents. Oral or rectal administration of a nonabsorbable antibiotic such as neomycin may reduce enteric bacteria responsible for ammonia production. Flumazenil, a benzodiazepine antagonist, may reverse early hepatic encephalopathy.

Controlled trials have shown a worsened outcome of fulminant hepatic failure in patients treated with corticosteroids. However, immunosuppressive therapy may be effective in fulminant autoimmune hepatitis. The antiviral drug pleconaril is the treatment of choice for fulminant enteroviral hepatitis in the neonate. Various approaches have been used to assist the liver in removing neuroactive toxins, such as plasmapheresis or perfusion of the patient's plasma through a column of charcoal or other binding resins. Although patients may experience an improvement in encephalopathy, little evidence shows that these treatments improve survival. Several liver assist devices containing cultured hepatocytes or liver cell lines are also being used experimentally in an effort to allow regeneration of a patient's liver or to temporize until a suitable organ donor becomes available. Orthotopic liver transplantation (OLT) may be lifesaving in patients who reach advanced stages of hepatic coma. Reduced-size allografts and living donor transplantation have been important advances in the treatment of infants with hepatic failure. Partial auxiliary orthotopic or heterotopic liver transplantation is successful in a small number of children and in some cases has allowed regeneration of the native liver and eventual withdrawal of immunosuppression (Chapter 349). OLT should not be done in patients with liver failure and neuromuscular dysfunction secondary to a mitochondrial disorder since progressive neurologic deterioration is likely to continue post transplant.

Prognosis.

Children with hepatic failure may fare somewhat better than adults, but overall mortality exceeds 70%. The prognosis may vary considerably with the cause of liver failure and stage of hepatic encephalopathy. With intensive medical support, survival rates of 50–60% occur with hepatic failure complicating acetaminophen overdose and with fulminant HAV or HBV infection. In contrast, recovery can be expected in

only 10–20% of patients with liver failure caused by non-A, non-B, non-C hepatitis or an acute onset of Wilson's disease. In patients who progress to stage IV coma (see Table 345–1), the prognosis is extremely poor. Major complications such as sepsis, severe hemorrhage, or renal failure increase the mortality. The prognosis is particularly poor in patients with liver necrosis and multiorgan failure. Studies indicate that jaundice for more than 7 days before the onset of encephalopathy, a prothrombin time more than 50?sec, and a serum bilirubin level more than 17.5?mg/dL (300?µmol/L) indicate a poor prognosis irrespective of the initial stage of hepatic coma. Survival of 50–75% is being achieved in patients with the poorest prognosis after orthotopic liver transplantation. Patients who recover from fulminant hepatic failure with only supportive care do not usually experience cirrhosis or chronic liver disease. Aplastic anemia is a common and usually fatal complication of fulminant hepatic failure secondary to sporadic non-A, non-B, non-C hepatitis.

Chapter 346 - Cystic Diseases of the Biliary Tract and Liver

Frederick J. Suchy

Cystic lesions of liver parenchyma or of the biliary system may be recognized initially during infancy and childhood. Their classification is not yet satisfactory. Pathologic features may be found in common among several of these disorders, but different patterns of inheritance indicate that their etiology is heterogeneous.

Choledochal Cysts.

These are congenital dilatations of the common bile duct that may cause progressive biliary obstruction and biliary cirrhosis. Cylindrical and spherical cysts of the extrahepatic ducts are the most common types. Segmental or diffuse dilatation can be observed. A diverticulum of the common bile duct or dilatation of the intraduodenal portion of the common duct (choledochocele) is a variant. Cystic dilatation of the intrahepatic bile ducts may be associated with a choledochal cyst.

The pathogenesis of choledochal cysts remains uncertain. Some reports have suggested that junction of the common bile duct and the pancreatic duct before their entry into the sphincter of Oddi may allow reflux of pancreatic enzymes into the common bile duct, causing inflammation, localized weakness, and dilatation of the duct. Other possibilities are that choledochal cysts represent malformations of the common duct or that they occur as part of the spectrum of an infectious disease that includes neonatal hepatitis and biliary atresia. Consistent with this theory, reovirus RNA has been detected in liver and biliary tissues of some infants with choledochal cysts.

Approximately 75% of cases appear during childhood. The infant typically presents with cholestatic jaundice; severe liver dysfunction including ascites and coagulopathy can rapidly evolve if biliary obstruction is not relieved. An abdominal mass is rarely palpable. In an older child, the classic triad of abdominal pain, jaundice, and mass occurs in fewer than 33% of patients. Features of acute cholangitis (fever, right upper quadrant tenderness, jaundice, leukocytosis) may be present. The diagnosis is made by ultrasonography; choledochal cysts have been identified prenatally using this technique. Magnetic resonance cholangiography is useful in the preoperative

assessment of choledochal cyst anatomy.

The treatment of choice is primary excision of the cyst and a Roux-en-Y choledochojejunostomy. Simple drainage into the small bowel is less satisfactory owing to a risk for development of carcinoma in the residual cystic tissue. The postoperative course may be complicated by recurrent cholangitis or stricture at the anastomotic site.

Cystic Dilatation of the Intrahepatic Bile Ducts (Caroli Disease).

Congenital, saccular dilatation may affect several segments of the intrahepatic bile ducts; the dilated ducts are lined by cuboidal epithelium and are in continuity with the main duct system, which is usually normal. Caroli actually described two variants: *Caroli disease,* characterized by ectasias of the intrahepatic bile ducts without other abnormalities, and *Caroli syndrome,* in which congenital ductal dilatation is associated with features of congenital hepatic fibrosis and the renal lesion of autosomal recessive polycystic renal disease. Caroli syndrome is more common, but both varieties may occur in the same family and are inherited in an autosomal recessive fashion. Choledochal cysts have also been associated with Caroli disease. There is a marked predisposition to ascending cholangitis and calculus formation within the abnormal bile ducts.

Affected patients usually experience symptoms of acute cholangitis as children or young adults. Fever, abdominal pain, mild jaundice, and pruritus occur; and a slightly enlarged, tender liver is palpable. Elevated alkaline phosphatase (ALP) activity, direct-reacting bilirubin levels, and leukocytosis may be observed during episodes of acute infection. In patients with Caroli syndrome, clinical features may be due to a combination of recurring bouts of cholangitis reflecting the intrahepatic ductal abnormalities and portal hypertensive bleeding resulting from hepatic fibrosis. Ultrasonography shows the dilated intrahepatic ducts, but definitive diagnosis and extent of disease must be determined by percutaneous transhepatic, endoscopic, or magnetic resonance cholangiography.

Cholangitis and sepsis are treated with appropriate antibiotics. Calculi may require surgery. Partial hepatectomy may be curative in rare cases when disease is confined to a single lobe. The prognosis is otherwise guarded, largely owing to difficulties in controlling cholangitis and biliary lithiasis and to a significant risk for developing cholangiocarcinoma. Liver transplantation may be required.

Congenital Hepatic Fibrosis.

This is an autosomal recessive disorder characterized pathologically by diffuse periportal and perilobular fibrosis in broad bands that contain distorted bile ductlike structures and that often compress or incorporate central or sublobular veins. The ductlike structures may become dilated to the point of microcyst formation but do not communicate with the biliary tract. Irregularly shaped islands of liver parenchyma contain normal-appearing hepatocytes. Caroli disease and choledochal cysts have been associated (see earlier discussion). About 75% of patients have renal disease, such as renal tubular ectasia, nephronophthisis, or autosomal recessive polycystic renal disease. Congenital hepatic fibrosis also occurs as part of the COACH syndrome (*C*erebellar vermis hypoplasia, *O*ligophrenia, congenital *A*taxia, *C*oloboma, and *H*epatic fibrosis). Congenital hepatic fibrosis has been described in children with a congenital disorder of glycosylation caused by mutations in the gene encoding phosphomannose isomerase (Chapter 76.6).

The disorder usually has its clinical onset in childhood, with hepatosplenomegaly or with bleeding secondary to portal hypertension. Cholangitis may occur in patients who have associated abnormalities of bile ducts.

Hepatocellular function is well preserved. Serum aminotransferase activities and bilirubin levels are usually normal; serum ALP activity may be slightly elevated. The serum albumin level and prothrombin time are normal. Liver biopsy is usually required for diagnosis.

Treatment of this disorder should focus on control of bleeding from esophageal varices. Infrequent mild bleeding episodes may be managed by endoscopic sclerotherapy or band ligation of the varices. After more severe hemorrhage, portacaval anastomosis may bring relief of portal hypertension. The prognosis may be greatly improved by a shunting procedure, but survival in some patients may be limited by renal failure.

A **solitary liver cyst** (nonparasitic) rarely occurs in childhood. Abdominal distention and pain may be present, and a poorly defined right upper quadrant mass may be palpable. These benign lesions are best left undisturbed unless they compress adjacent structures or a complication occurs, such as hemorrhage into the cyst.

Autosomal Dominant Polycystic Kidney Disease (ADPKD) (Chapter 513.2).

ADPKD, a common inherited disease, affects 1/1,000 live births. It is characterized by progressive renal cyst development and enlargement and an array of extrarenal manifestations. There is a high degree of intrafamilial and interfamilial variability in the clinical expression of the disease.

At least three genetic loci are seen in ADPKD. The PKD 1 gene (accounting for 85% of cases) is on chromosome 16p13.3 and encodes for a novel protein called *polycystin,* which may have a potential role in cell-cell and cell-matrix interactions. The PKD 2 gene (~15% of cases) is on chromosome 4q13–23 and encodes for a protein thought to interact in some fashion with polycystin. A third locus for autosomal dominant polycystic liver disease not associated with kidney cysts has been found on chromosome 19p13.2–13.1.

Multiple hepatic lesions have been associated with ADPKD and include the ductal plate malformation with cystic communicating duct elements, dilated and apparently noncommunicating cysts, and biliary microhamartomas (the so-called von Meyenburg complexes). Segmental dilatation of the intrahepatic ducts (Caroli disease) and congenital hepatic fibrosis have been reported. Approximately 50% of patients with renal failure have demonstrable hepatic cysts that are not in continuity with the biliary tract. The hepatic cysts increase with age but are extremely uncommon before the age of 16 yr. Hepatic cystogenesis appears to be influenced

by estrogens. Although the frequency of cysts is similar in males and females, the development of large hepatic cysts is largely a complication in females. Hepatic cysts are often asymptomatic but may cause pain and are occasionally complicated by hemorrhage, infection, jaundice from bile duct compression, portal hypertension with variceal bleeding, or hepatic venous outflow obstruction from mechanical compression of hepatic veins, resulting in tender hepatomegaly and exudative ascites. Cholangiocarcinoma may occur. Selected patients with severe symptomatic polycystic liver disease and favorable anatomy benefit from liver resection or fenestration.

Subarachnoid hemorrhage may result from the associated cerebral arterial aneurysms.

Autosomal Recessive Polycystic Kidney Disease (ARPKD) (Chapter 513.1 **).**

ARPKD presents predominantly in childhood. Bilateral enlargement of the kidneys is caused by a generalized dilatation of the collecting tubules. The disorder is invariably associated with congenital hepatic fibrosis and various degrees of biliary ductal ectasia. The gene responsible for ARPKD has been localized to chromosome 6p21, with no evidence for genetic heterogeneity among the different clinical phenotypes.

ARPKD normally presents in early life, often shortly after birth, and is generally more severe than ADPKD. Patients with ARPKD may die in the perinatal period owing to renal failure or lung dysgenesis. The kidneys in these patients are usually markedly enlarged and dysfunctional. Respiratory failure may result from compression of the chest by grossly enlarged kidneys, from fluid retention, or from concomitant pulmonary hypoplasia. The clinical pathologic findings within a family tend to breed true, although there has been some variability in the severity of the disease and the time for presentation within the same family.

The liver in patients with ARPKD demonstrates various degrees of periportal fibrosis, bile ductular hyperplasia, and biliary dysgenesis. Liver disease and complications from hepatic fibrosis are most likely to be clinically significant in patients whose kidney disease allows prolonged survival. The most prominent clinical problem in older patients with ARPKD and congenital hepatic fibrosis is portal hypertension. Although portal hypertensive bleeding may occur during the first year of life, it more commonly presents in older children with hematemesis or melena. Firm or hard hepatomegaly is usually present. Splenomegaly is a frequent finding accompanied by hypersplenism. Owing to dilatation of the intrahepatic bile ducts, these patients are at increased risk of bacterial cholangitis. Caroli disease or a congenital, segmental, saccular dilatation of the intrahepatic bile ducts may coexist with congenital hepatic fibrosis and ARPKD.

Hemorrhage from esophageal varices may be initially managed by using endoscopic sclerotherapy or banding. Some patients with well-preserved hepatic function may benefit from a selective portacaval shunt. Biliary sepsis should be aggressively treated. Recurrent bouts of bacterial cholangitis can lead to progressive loss of hepatic function. Rare patients may have unilateral involvement that can be treated by hepatic resection. Hepatic transplantation may be required for patients with hepatic failure.

Variable abnormalities of bile ducts (irregular dilatation, proliferation, cysts) and portal fibrosis may be associated with Meckel's syndrome, 17–18 trisomy, tuberous sclerosis, and asphyxiating thoracic dystrophy.

Chapter 347 - Diseases of the Gallbladder

Frederick J. Suchy

Anomalies.

The gallbladder is congenitally absent in about 0.1% of the population. Hypoplasia or absence of the gallbladder may be associated with extrahepatic biliary atresia or cystic fibrosis. Duplication of the gallbladder occurs rarely.

Acute Hydrops (Box 347–1).

Acute noncalculous, noninflammatory distention of the gallbladder may occur in infants and children. It is defined by the absence of calculi, bacterial infection, or congenital anomalies of the biliary system. The disorder may complicate acute infections, but the cause is often not identified. Hydrops of the gallbladder may also develop in patients receiving long-term parenteral nutrition, presumably as a result of gallbladder stasis during the period of enteral fasting. Hydrops is distinguished from acalculous cholecystitis by the absence of a significant inflammatory process and a generally benign prognosis.

Affected patients usually have right upper quadrant pain with a palpable mass. Fever, vomiting, and jaundice may be present and are usually associated with a systemic illness such as streptococcal infection. Ultrasonography shows a markedly distended, echo-free gallbladder, without dilatation of the biliary tree. Acute hydrops is usually treated conservatively and rarely needs cholecystostomy and drainage. At laparotomy, a large, edematous gallbladder is found to contain white, yellow, or green bile.

Box 347-1. Conditions Associated with Hydrops of the Gallbladder

- Kawasaki disease
- Streptococcal pharyngitis
- Staphylococcal infection
- Leptospirosis
- Ascariasis
- Threadworm
- Sickle cell crisis
- Typhoid fever
- Thalassemia
- Total parenteral nutrition
- Prolonged fasting
- Viral hepatitis
- Sepsis
- Henoch-Schönlein purpura
- Mesenteric adenitis
- Necrotizing enterocolitis

Obstruction of the cystic duct by mesenteric adenopathy is occasionally observed. Cholecystectomy is required if the gallbladder is gangrenous. Pathologic examination of the gallbladder wall shows edema and mild inflammation. Cultures of bile are usually sterile. Treatment of gallbladder hydrops is usually nonsurgical, with a focus on supportive care and managing the intercurrent illness. Spontaneous resolution and return of normal gallbladder function usually occur over a period of several weeks.

Cholecystitis and Cholelithiasis.

Acute acalculous cholecystitis is uncommon in children and is usually caused by infection. Pathogens include streptococci (groups A and B), gram-negative organisms, particularly *Salmonella,* and *Leptospira interrogans.* Parasitic infestation with ascaris or *Giardia lamblia* may be found. Acalculous cholecystitis may rarely follow abdominal trauma or burn injury or may be associated with a systemic vasculitis, such as periarteritis nodosa.

Clinical features include right upper quadrant or epigastric pain, nausea, vomiting, fever, and jaundice. Right upper quadrant guarding and tenderness are present. Ultrasonography discloses an enlarged, thick-walled gallbladder, without calculi. Serum alkaline phosphatase activity and direct-reacting bilirubin levels are elevated. Leukocytosis is usual.

The diagnosis is confirmed at laparotomy. Cholecystectomy and treatment of the systemic infection are required.

Cholelithiasis is relatively rare in otherwise healthy children, occurring more commonly in patients with various predisposing disorders (Box 347–2). Gallstones, composed of a mixture of cholesterol, bile pigment, calcium, and inorganic matrix, are common. In children, more than 70% of gallstones are the pigment type, 15–20% are cholesterol stones, and the remainder is of unknown composition. Stones of pure cholesterol or bile pigment may also occur. Biliary dyskinesia, a disorder of impaired gallbladder contractility, is an abnormality predisposing to gallstones in late childhood and teenage years.

Acute or chronic cholecystitis is often associated with gallstones. The acute form may be precipitated by impaction of a stone in the cystic duct. Proliferation of bacteria within the obstructed gallbladder lumen can contribute to the process and lead to biliary sepsis. Chronic calculous cholecystitis is more common. It may develop insidiously or follow several attacks of acute cholecystitis. The gallbladder epithelium commonly becomes ulcerated and scarred.

The most important clinical feature of cholelithiasis is recurrent abdominal pain, which is often colicky and localized to the right upper quadrant. An older child may have intolerance for fatty foods. Acute cholecystitis may be the first manifestation, with fever, pain in the right upper quadrant, and often a palpable mass. Pain may radiate to an area just below the right scapula. A plain roentgenogram of the abdomen may reveal opaque calculi, but radiolucent (cholesterol) stones are not visualized. Accordingly, ultrasonography is the method of choice for gallstone detection. Hepatobiliary scintography is a valuable

Box 347-2. Conditions Associated with Cholelithiasis

Chronic hemolytic disease (sickle cell anemia, spherocytosis)

Obesity

Ileal resection or disease

Cystic fibrosis

Chronic liver disease

Crohn disease

Prolonged parenteral nutrition

Prematurity with complicated medical or surgical course

Prolonged fasting or rapid weight reduction

Treatment of childhood cancer

Abdominal surgery

Pregnancy

adjunct in that failure to visualize the gallbladder provides evidence of cholecystitis.

Cholecystectomy is usually curative; operative cholangiography should be done at the time of surgery to preclude common duct calculi. Dissolution of cholesterol gallstones with oral ursodeoxycholic acid is ineffective in the treatment of gallstones in children, except in terms of relieving symptoms while on treatment.

Laparoscopic cholecystectomy is commonly performed in symptomatic infants and children with cholelithiasis. Common bile duct stones are unusual in children, occurring in 2–6% of cases with cholelithiasis, often in association with obstructive jaundice and pancreatitis. Endoscopic retrograde cholangiography with stone extraction performed before or after laparoscopic cholecystectomy is the procedure of choice in this setting.

Patients with hemolytic disease (including sickle cell anemia, the thalassemias, and red blood cell enzymopathies) and Wilson disease are at increased risk for black pigment cholelithiasis. In sickle cell disease, pigment gallstones may develop before age 4 yr and have been reported in 17% to 33% of patients aged 2 to 18 yr.

Cirrhosis and chronic cholestasis also increase the risk for pigment gallstones. Increasing numbers of sick premature infants are being found to have gallstones; their treatment is often complicated by such factors as bowel resection, necrotizing enterocolitis, prolonged parenteral nutrition without enteral feeding, cholestasis, frequent blood transfusions, and use of diuretics. Cholelithiasis in premature infants is often asymptomatic and may resolve spontaneously. Brown pigment stones have been found in patients with obstructive jaundice and infected intra- and extrahepatic bile ducts. These stones are usually radiolucent, owing to a lower content of calcium phosphate and carbonate and a higher amount of cholesterol than in black pigment stones.

Cholesterol cholelithiasis in children most frequently affects obese adolescent girls. Cholesterol gallstones are found also in children with disturbances of the enterohepatic circulation of bile acids, including patients with ileal disease and bile acid malabsorption, such as those with ileal resection, ileal Crohn disease, and cystic fibrosis. Pigment stones may also occur in these patients.

Cholesterol gallstone formation seems to result from an excess of cholesterol in relation to the cholesterol-carrying capacity of micelles in bile. Supersaturation of bile with cholesterol leading to crystal and stone formation could result from decreased bile acid or from an increased cholesterol concentration in bile. Other initiating factors that may be important in stone formation include gallbladder stasis or the presence in bile of abnormal mucoproteins or bile pigments that may serve as a nidus for cholesterol crystallization.

Chapter 348 - Portal Hypertension and Varices

Frederick J. Suchy

Portal hypertension—defined as an elevation of portal pressure above 10–12?mm Hg—is a major cause of morbidity and mortality in children with liver disease. The normal portal venous pressure is approximately 7?mm Hg. The clinical features of the various forms of portal hypertension may be similar, but the associated complications, management, and prognosis can vary significantly and depend on whether the process is complicated by hepatic insufficiency.

Etiology.

Numerous causes of portal hypertension result from obstruction to portal blood flow anywhere along the course of the portal venous system. The various disorders associated with portal hypertension are outlined in Box 348–1 . Portal hypertension may occur as a result of prehepatic, intrahepatic, or posthepatic obstruction to the flow of portal blood.

Extrahepatic portal vein obstruction is an important cause of portal hypertension in childhood. The obstruction may occur at any level of the portal vein. Umbilical infection with or without a history of catheterization of the umbilical vein may be causal in neonates. The infection can spread potentially from the umbilical vein to the left branch of the portal vein and eventually to the main portal venous channel. Intra-abdominal infections

Box 348-1. Causes of Portal Hypertension

EXTRAHEPATIC PORTAL HYPERTENSION

Portal Vein Obstruction

- Portal vein thrombosis or cavernous transformation
- Splenic vein thrombosis

Increased Portal Flow

- Arteriovenous fistula

INTRAHEPATIC PORTAL HYPERTENSION

Hepatocellular Disease

- Acute and chronic viral hepatitis
- Cirrhosis
- Congenital hepatic fibrosis
- Wilson disease
- a_1 -Antitrypsin deficiency
- Glycogen storage disease type IV
- Hepatotoxicity
    - Methotrexate
    - Parenteral nutrition

Biliary Tract Disease

- Extrahepatic biliary atresia

Biliary Tract Disease

- Extrahepatic biliary atresia
- Cystic fibrosis
- Choledochal cyst
- Sclerosing cholangitis
- Intrahepatic bile duct paucity

Idiopathic Portal Hypertension

Postsinusoidal Obstruction

- Budd-Chiari syndrome
- Veno-occlusive disease

---

including acute appendicitis and primary peritonitis can be causal in older children. Portal vein thrombosis has also been associated with neonatal dehydration and systemic infection. In older children, inflammatory bowel disease can be associated with a hypercoagulable state and portal venous obstruction. Thrombosis of the portal vein has also occurred in association with biliary tract infections and primary sclerosing cholangitis. Portal vein thrombosis has also been associated with hypercoagulable states such as factor V Leiden deficiency or protein C and protein S deficiencies. The portal vein can be replaced by a fibrous remnant or contain an organized thrombus. Obstruction by a web or diaphragm can also occur. At least half of reported cases have no defined cause.

Uncommonly, presinusoidal hypertension can be caused by increased flow through the portal system as a result of a congenital or acquired arteriovenous fistula.

The intrahepatic causes of portal hypertension are numerous. Obstruction to flow can occur on the basis of a presinusoidal process including acute and chronic hepatitis, congenital hepatic fibrosis, or schistosomiasis. Portal infiltration with malignant cells or granulomas can also contribute. An idiopathic form of portal hypertension characterized by splenomegaly, hypersplenism, and portal hypertension without occlusion of portal or splenic veins and with no obvious disease in the liver has been described. In some patients, noncirrhotic portal fibrosis has been observed.

Cirrhosis is the predominant cause of portal hypertension and is related to obstruction of blood through the portal vein. The numerous causes of cirrhosis include recognized disorders such as extrahepatic biliary atresia, metabolic liver

disease such as a_1 -antitrypsin deficiency, Wilson's disease, glycogen storage disease type IV, hereditary fructose intolerance, and cystic fibrosis.

Postsinusoidal causes of portal hypertension are also observed during childhood. The Budd-Chiari syndrome occurs with obstruction to hepatic veins anywhere between the efferent hepatic veins and the entry of the inferior vena cava into the right atrium. In most cases, no specific cause can be found, but the thrombosis can complicate neoplasms, collagen vascular disease, infection, and trauma. Veno-occlusive disease is the most frequent cause of hepatic vein obstruction in children. In this disorder, occlusion of the centrilobular venules or sublobular hepatic veins occurs. The disorder occurs after total body irradiation with or without cytotoxic drug therapy that is commonly used before bone marrow transplantation. The disease has also occurred after ingestion of herbal remedies containing the pyrrolizidine alkaloids, which are sometimes taken as medicinal teas.

Pathophysiology.

The primary hemodynamic abnormality in portal hypertension is increased resistance to portal blood flow. This is the case whether the resistance to portal flow has an intrahepatic cause such as cirrhosis or is due to portal vein obstruction. Portosystemic shunting should decompress the portal system and thus significantly lower portal pressures. However, despite the development of significant collaterals deviating portal blood into systemic veins, portal hypertension is maintained by an overall increase in portal venous flow and thus maintenance of portal hypertension. A hyperdynamic circulation is achieved by tachycardia, an increase in cardiac output, and decreased systemic vascular resistance. Splanchnic dilatation also occurs. Overall, the increase in portal flow likely contributes to an increase in variceal transmural pressure. The increase in portal blood flow is related to the contribution of hepatic and collateral flow; the actual portal blood flow reaching the liver is reduced. It is also likely that hepatocellular dysfunction and portosystemic shunting lead to the generation of various humoral factors that cause vasodilatation and an increase in plasma volume.

Many of the portal hypertension complications can be accounted for by the development of a remarkable collateral circulation. Collateral vessels may form prominently in areas in which absorptive epithelium joins stratified epithelium, particularly in the esophagus or anorectal region. The superficial submucosal collaterals, especially those in the esophagus and stomach and to a lesser extent those in the duodenum, colon, or rectum, are prone to rupture and bleeding under increased pressure. In portal hypertension, the vascularity of the stomach is also abnormal and demonstrates prominent submucosal arteriovenous communications between the muscularis mucosa and dilated precapillaries and veins. The resulting lesion—a vascular ectasia—has been called *congestive gastropathy* and contributes to a significant risk of bleeding from the stomach.

Clinical Manifestations.

Bleeding from esophageal varices is the most common presentation. In patients with underlying hepatic disease, physical examination may show jaundice and stigmata of cirrhosis such as palmar erythema and vascular telangiectasias. Ascites may be present in patients with intrahepatic causes of portal hypertension but is uncommon with portal vein obstruction. Dilated cutaneous collateral vessels carrying blood from the portal to systemic circulation may be apparent in the periumbilical region. In the absence of clinical or biochemical features of liver disease and a liver of normal size, portal vein obstruction is most likely. However, well-compensated cirrhosis cannot be completely ruled out under these conditions. An enlarged, hard liver with minimal disturbance of hepatic function suggests the possibility of congenital hepatic fibrosis. Hemorrhage, particularly in children with portal vein obstruction, may be precipitated by minor febrile, intercurrent illness. The mechanism is often unclear; aspirin or other nonsteroidal anti-inflammatory drugs may be a contributing factor by damaging the integrity of a congested gastric mucosa or interfering with platelet function. Coughing during a respiratory illness can also increase intravariceal pressure. The bleeding may become apparent with hematemesis or with melena. Gastrointestinal hemorrhage can also originate from portal hypertensive gastropathy or from gastric, duodenal, peristomal, or rectal varices. Splenomegaly, sometimes with hypersplenism, is the next most common presenting feature in portal vein obstruction and may be discovered first on routine physical examination. Because more than half of patients in many series with portal vein obstruction do not experience bleeding until after age 6 yr, the diagnosis should be suggested in a child without hepatocellular disease who had a complicated neonatal course and in whom asymptomatic splenomegaly later developed.

Children with portal hypertension, regardless of the underlying cause, may have recurrent bouts of life-threatening hemorrhage. In patients with portal vein obstruction and normal hepatic function, the bleeding usually stops spontaneously. In patients with intrahepatic disease, the combination of portal hypertension and poor liver synthetic ability (coagulopathy) can make bleeding much more difficult to control. Moreover, esophageal hemorrhage and cirrhosis may have injurious effects

---

on the liver, further impairing hepatic function and sometimes precipitating jaundice, ascites, and encephalopathy.

Diagnosis.

In patients with established chronic liver disease or in those in whom portal vein obstruction is suspected, an experienced ultrasonographer should be able to demonstrate the patency of the portal vein. In addition, the use of Doppler flow ultrasonography may demonstrate the direction of flow within the portal system. The pattern of flow correlates with the severity of cirrhosis and encephalopathy. Hepatopetal flow is more likely to be associated with variceal bleeding. Ultrasonography is also effective in detecting the presence of esophageal varices. Another important feature of extrahepatic portal vein obstruction is so-called cavernous transformation of the portal vein in which an extensive complex of small collateral vessels has formed to bypass the obstruction. Various other imaging techniques also contribute to further definition of the portal vein anatomy but are required less often; computed tomography and magnetic resonance imaging provide similar information to ultrasonography. Selective arteriography of the celiac axis, superior mesenteric artery, and splenic vein may be useful in precise mapping of the extrahepatic vascular anatomy. This is not required to establish a diagnosis but may

prove valuable in planning surgical decompression of portal hypertension.

Endoscopy is the most reliable method for detecting esophageal varices and for identifying the source of gastrointestinal bleeding. Although bleeding from esophageal or gastric varices is most common in children with portal hypertension, up to one third of patients, particularly those with cirrhosis, may have bleeding from some other source such as portal hypertensive gastropathy or gastric or duodenal ulcerations. There is a strong correlation between variceal size as assessed endoscopically and the probability of hemorrhage. Red spots apparent over varices at the time of endoscopy are a strong predictor of imminent hemorrhage.

Treatment.

The therapy of portal hypertension can be divided into emergency treatment of potentially life-threatening hemorrhage and prophylaxis directed at prevention of initial or subsequent bleeding. It must be emphasized that many trials of therapy are based on experience with adults with portal hypertension.

Treatment of patients with variceal hemorrhage must focus on fluid resuscitation initially in the form of crystalloid infusion followed by the replacement of red blood cells. Correction of coagulopathy by administration of vitamin K or the infusion of platelets or fresh frozen plasma, or both therapies, may be required. A nasogastric tube should be placed to document the presence of blood within the stomach and to monitor for ongoing bleeding. An H_2 receptor blocker such as ranitidine should be given intravenously to reduce the risk of bleeding from gastric erosions. In most patients, particularly those with extrahepatic portal hypertension and with normal hepatic synthetic function, bleeding usually stops spontaneously. Care should be taken in fluid resuscitation of children after bleeding to avoid producing an excessively high venous pressure and an increased risk for further bleeding.

Pharmacologic therapy to decrease portal pressure may be considered in patients with continued bleeding. Vasopressin or one of its analogs has been commonly used and is thought to act by increasing splanchnic vascular tone and thus decreasing portal blood flow. Vasopressin is administered initially with a bolus of 0.33?U/kg over 20?min followed by a continued infusion of the same dose on an hourly basis or a continuous infusion of 0.2?U/1.73?m^2 /min. The drug has a half-life of approximately 30?min. Its use may be limited by the side effects of vasoconstriction, which can impair cardiac function and perfusion to the heart, bowel, and kidneys and may also, as a result, exacerbate fluid retention. Nitroglycerin, usually given as a portion of a skin patch, has also been used to decrease portal pressure and, when used in conjunction with vasopressin, may ameliorate some of its untoward effects. The somatostatin analog octreotide decreases splanchnic blood flow with fewer side effects. Although studies in adults are promising, its use and efficacy in children have not been well evaluated.

After an episode of variceal hemorrhage or in patients in whom bleeding cannot be controlled, endoscopic sclerosis of esophageal varices is an important option. In this technique, sclerosants are injected either intravariceally or paravariceally until bleeding has stopped. Although bleeding may be controlled acutely in most cases, further sessions of sclerotherapy are required to achieve temporary obliteration of the varices. Treatments may be associated with further bleeding, bacteremia, esophageal ulceration, and stricture formation. Most centers do not perform endoscopic sclerotherapy of varices prophylactically but use the procedure as a bridge to the time of liver transplantation or until collateral circulation develops in extrahepatic portal vein obstruction. Endoscopic elastic band ligation of varices has been introduced as a safer and potentially as effective therapy for obliteration of varices.

In patients who continue to bleed despite pharmacologic and endoscopic methods to control hemorrhage, a Sengstaken-Blakemore tube may be placed to stop hemorrhage by mechanically compressing esophageal and gastric varices. The device may be the only option to control life-threatening hemorrhage but carries a significant rate of complications and a high rate of bleeding when the device is removed. It poses a particularly high risk for pulmonary aspiration, and the tube is not well tolerated in children without significant sedation.

Various surgical procedures have been devised to divert portal blood flow and to decrease portal pressure. A portacaval shunt diverts nearly all of the portal blood flow into the subhepatic inferior right vena cava. Although portal pressure is significantly reduced, because of the significant diversion of blood from the liver, patients with parenchymal liver disease have a marked risk for hepatic encephalopathy. More selective shunting procedures, such as mesocaval or distal splenorenal shunt, may effectively decompress the portal system while allowing a greater amount of portal blood flow to the liver. The small size of the vessels makes these operations technically challenging in infants and small children, and there is a significant risk of failure as a result of shunt thrombosis. Therefore, orthotopic liver transplantation represents a much better therapy for portal hypertension resulting from intrahepatic disease. A prior portosystemic shunting operation does not preclude a successful liver transplantation but makes the operation technically more difficult. Portosystemic shunting may remain an option in children with extrahepatic portal hypertension, particularly in those patients who are suffering from potentially life-threatening hemorrhage not effectively controlled by other measures and who reside a great distance from emergency medical care. A transjugular intrahepatic portosystemic shunt (TIPS), in which a stent is placed by an interventional radiologist between the right hepatic vein and the right or left branch of the portal vein, can aid in the management of portal hypertension in children, especially in those needing temporary relief before liver transplantation. However, the TIPS procedure may precipitate hepatic encephalopathy and is prone to thrombosis.

Long-term treatment with nonspecific ß-blockers such as propranolol has been used extensively in adults with portal hypertension. These agents may act by lowering cardiac output and portal perfusion. Evidence in adult patients shows that ß-blockers may reduce the incidence of variceal hemorrhage and improve long-term survival. A therapeutic effect is thought to result when the pulse rate is reduced by at least 25%. There is limited published experience with the use of this therapy in children.

Prognosis.

Portal hypertension secondary to intrahepatic disease has a poor prognosis. Portal hypertension is usually progressive

in these patients and is often associated with deteriorating liver function. Efforts should be directed toward prompt treatment of acute bleeding and prevention of recurrent hemorrhage with available methods. Patients with progressive liver disease and significant esophageal varices ultimately require orthotopic liver transplantation. Liver transplantation might also be considered for patients with portal hypertension secondary to hepatic vein obstruction or resulting from severe veno-occlusive disease.

In patients with portal vein obstruction, episodes of bleeding may become less frequent and severe with age as a collateral circulation develops. Most patients can be treated conservatively with endoscopic sclerotherapy when necessary. However, children may continue to experience significant bleeding during adolescence and may eventually require a portosystemic shunting procedure.

Chapter 349 - Liver Transplantation

Kenneth L. Cox

Liver transplantation is standard therapy for children with end-stage liver disease, life-threatening hepatic metabolic disorders, and cancers of the liver. With current immunosuppression and surgical techniques, 1- and 5-yr survival rates for children after liver transplantation are 84% and 79%, respectively. One half of pediatric liver transplant recipients are younger than 2 yr of age at the time of transplant and have a significantly poorer 1-yr survival rate (81%) as compared with older children (87%). Approximately, 500 children in the United States undergo liver transplantation each year with 10% having more than one organ transplanted simultaneously, which usually includes either a kidney or small intestine. The most frequent indication is extrahepatic biliary atresia after a failed portoenterostomy (Kasai) procedure. Metabolic liver disease and acute hepatic necrosis are next in frequency (Table 349–1). The decision to transplant in patients with metabolic liver disease includes the following considerations: Is it hepatic in origin, can it be successfully treated medically, and are the extrahepatic manifestations reversible?

Early referral to a transplant center is important so that patients and their families may be evaluated and treated in a timely fashion. Medical and psychological issues are assessed to determine the appropriateness of transplant, optimal management,

and urgency. Age (<1 yr), growth failure (defined as height or weight 2 standard deviations below normal), hyperbilirubinemia, hypoalbuminemia, and coagulopathy as indicated by prolonged international normalized ratio (INR) have been predictive of increased morbidity and mortality from liver disease and are used to determine the urgency for liver transplantation. Other variables that also indicate the need for liver transplantation are ascites, encephalopathy, variceal bleeding, and renal failure. Prompt referral of patients with fulminant hepatic failure is critical because a majority quickly die without liver transplantation. Counseling families about the special needs of children with chronic illness improves the psychosocial outcome. Early evaluation allows sufficient time to find a donor and for families to learn about liver transplantation.

Pretransplantation management is critical to the success of the procedure and to limiting morbidity from the liver disease. Portoenterostomies (the Kasai operation) should be performed in children with biliary atresia because it often delays and occasionally obviates the need for liver transplantation. Even children with biliary atresia who are over 3 mo of age may benefit from this procedure. Areas of major importance are nutrition and immunizations. Patients with liver disease have malabsorption as well as anorexia, which lead to growth retardation. Growth retardation is inversely correlated with age and is reversible in a majority of children after liver transplantation. Formula containing medium-chain triglycerides is helpful because bile salts are not necessary for their absorption. Caloric requirements may be as high as 150?kcal/kg/24?hr. Nocturnal nasogastric tube feedings and intravenous nutrition, especially lipids, may be required because of the anorexia and malabsorption. Fat-soluble vitamin deficiencies must be prevented by providing vitamin supplements. Vitamin E deficiency (ataxia, peripheral neuropathy, gross motor delay) is best avoided by using a well-absorbed preparation containing d-a-tocopherol polyethylene glycol succinate. Vitamin D deficiency–associated bone disease is prevented with oral preparations of 25-hydroxyvitamin D_3 . Early changes of vitamin A deficiency appear in the conjunctiva and cornea; they are prevented by

using an oral, water-soluble preparation of vitamin A. Vitamin K deficiency is commonly encountered as a prolonged prothrombin time, which may respond to oral supplementation, but often requires parenteral vitamin K. Vitamin and fat absorption may be enhanced with oral ursodeoxycholic acid as a choleretic (increases bile flow into the intestine) and an intraluminal bile acid. Prothrombin time and serum levels

of vitamins E, D, and A should be monitored. Iron deficiency due to occult blood loss and zinc deficiency associated with chronic diarrhea may occur. Immunizations should be given for hepatitis A and B to avoid additional hepatic injury caused by these infections, and those containing live viruses (measles-mumps-rubella, varicella) should be given on schedule because immunosuppression after transplantation may prevent administration.

Medical management should also be directed toward control of variceal bleeding, ascites, encephalopathy, coagulopathy, and sepsis. While waiting for transplantation, morbidity and mortality from liver failure can be reduced by prompt diagnosis and aggressive treatment of these complications.

The success of *transplantation* has been enhanced by better preservation of the organ (up to 18?hr ex vivo with <2% primary non-function), refinement of surgical techniques, and advances in immunosuppressive therapy. In pediatrics, the donor pool size has been expanded by using a lobe or segment of the liver from a cadaver or living donor and by using ABO blood type mismatch. Living related donation using the right lobe of the liver has recently been successful in adolescent and adult recipients. Most frequently, the biliary tract in young children is connected to a Roux-en-Y loop of jejunum and direct vascular connections are made. Donor venous grafts are occasionally used if pretransplant portal vein thrombosis is present. Steroids and either cyclosporine (Sandimmune or Neoral) or tacrolimus (Prograf, FK506) are standard therapies to prevent rejection. Many children are weaned off steroids within 1 yr of the transplant. Compared with cyclosporine (Sandimmune), tacrolimus has been associated with lower rates of acute and chronic rejection. The water-soluble microemulsion of cyclosporine (Neoral) has been better absorbed than the bile salt-dependent, fat soluble form (Sandimmune) and may be more comparable to tacrolimus in the prevention of rejection. Hirsutism and gingival hyperplasia are specific side effects of cyclosporine. Post-transplant lymphoproliferative disease (PTLD) occurs in 4–11% of children, is associated with high doses of immunosuppression and Epstein-Barr virus (EBV) infection, and has resulted a 10–20% mortality rate. The morbidity and mortality from PTLD has been reduced by early diagnoses with frequent monitoring of EBV serology and blood EBV PCR and by lowering immunosuppression as soon as infection is detected. Blood pressure and creatinine clearance should be monitored because hypertension and renal failure are common long-term complications, especially in children on high doses of cyclosporine or tacrolimus. When rejection has required high doses of cyclosporine or tacrolimus and/or continued use of steroids, azathioprine (Imuran), sirolimus (Rapamune), or mycophenolate mofetil (Cellcept) may control rejection and allow reduction of the doses of these more toxic drugs. Mouse anti-T cell monoclonal antibodies (OKT3) have been used to treat severe, steroid-resistant rejection. Less toxic, genetically engineered monoclonal anti-interleukin-2 (IL-2)-receptor antibodies can be used instead of OKT3.

Early *complications* include fluid shifts, electrolyte imbalance, renal dysfunction, and hypertension. Primary nonfunction of the graft or vascular complications, such as thrombosis of graft vessels, are ominous early problems that often result in death unless the graft is replaced within 48?hr. After this early phase, infection and organ rejection are the most frequent problems. Bacterial infections are most common, followed by viral (especially cytomegalovirus and adenovirus), fungal, and rarely parasitic (*Pneumocystis carinii*) infections. Hospital stays are usually 2–3 wk but may be several months. Late complications may arise (rejection, cyclosporine- or tacrolimus-induced renal dysfunction, EBV-associated PTLD). The latter may progress to lymphoma. Rejection in older children is often due to poor compliance in taking medications.

The *prognosis* for survivals is very encouraging. Most children have improvement in growth and development and the stigmata of chronic liver disease resolve. Children and their families resume more normal lives. Close follow-up of medical and psychosocial issues is necessary. Though some children may become tolerant of their graft and not need immunosuppression, many will reject up to 4 yr after immunosuppression has been discontinued. As a result, children are left on immunosuppression indefinitely until methods are developed that will identify those who are tolerant.

Section 7 - *Peritoneum*

Chapter 350 - Malformations

Jeffrey S. Hyams

Congenital peritoneal bands may be responsible for intestinal obstruction; numerous other anomalies may occur in the course of the development of the peritoneum but are rarely of clinical importance. Intra-abdominal herniations infrequently occur through ring-like formations produced by anomalous peritoneal bands. Absence of the omentum or its duplication occurs rarely. Omental cysts arise in obstructed lymphatic channels within the omentum. They may be congenital or may result from trauma and are usually asymptomatic. Abdominal pain or partial small bowel obstruction may result from compression or torsion of the small bowel from traction on the omentum.

Chapter 351 - Ascites

Jeffrey S. Hyams

Ascites is an accumulation of serous fluid within the peritoneal cavity. Multiple causes of ascites have been described (Box 351–1). In children, hepatic, renal, and cardiac disease are the most common causes.

The clinical hallmark of ascites is abdominal distention, but this may also be caused by other conditions, including gaseous distention, fecal retention, tumor masses, peritoneal hemorrhage, extreme bladder distention, pregnancy, and obesity. Considerable intraperitoneal fluid may accumulate before ascites is detectable by the five classic physical signs: bulging

flanks, flank dullness, shifting dullness, fluid wave, and the “puddle sign” (decreased auscultation of high-frequency vibrations in central abdomen when flicking side of abdomen with patient on hands and knees). Umbilical herniation may be associated with tense ascites. Ultrasound examination can detect small amounts of ascites.

The course, prognosis, and treatment of ascites depend entirely on the cause. Patients with any type of ascites are at increased risk for spontaneous bacterial peritonitis.

351.1 Chylous Ascites

Chylous ascites can result from an anomaly, injury, or obstruction of the intra-abdominal portion of the thoracic duct. Although uncommon, it can occur at any age. Causes include congenital malformations, peritoneal bands, generalized lymphangiomatosis, chronic inflammatory processes of the bowel, tumors, enlarged lymph nodes, previous abdominal surgery, and trauma.

In neonates, rapidly progressing abdominal distention is noted along with poor weight gain and loose stools. Peripheral edema is common. Massive chylous ascites may result in scrotal edema, inguinal and umbilical herniation, and respiratory embarrassment.

Diagnosis of chylous ascites depends on the demonstration of milky ascitic fluid obtained via paracentesis after a fat- containing feeding. Fluid analysis will reveal a high protein content, elevated triglycerides, and lymphocytosis. If the patient has had nothing by mouth, the fluid will appear serous. Hypoalbuminemia, hypogammaglobulinemia, and lymphopenia are common.

Treatment includes the provision of a high-protein, low-fat diet supplemented with medium-chain triglycerides that are absorbed directly into the portal circulation. Parenteral alimentation may be necessary if nutrition remains impaired on oral feedings and also in order to decrease lymph flow to facilitate sealing at the point of lymph leakage. Paracentesis should be repeated only if abdominal distention causes respiratory distress. Laparotomy may be indicated to search for the site of the leak if a trial of dietary management has been unsuccessful.

Chapter 352 - Peritonitis

Jeffrey S. Hyams

Inflammation of the peritoneal lining of the abdominal cavity may result from infectious, autoimmune, and chemical processes. Infectious peritonitis is usually defined as primary (spontaneous) or secondary. In primary peritonitis, the source of infection originates outside the abdomen and seeds the

peritoneal cavity via hematogenous or lymphatic spread. Secondary peritonitis arises from the abdominal cavity itself through either extension from or rupture of an intra-abdominal viscus or an abscess within an organ.

Peritonitis in the neonatal period may arise from a transplacental in utero infection; more frequently, it is the result of infection acquired during or shortly after birth. It may be a manifestation of septicemia, a direct extension from an umbilical infection or from perforation of the intestine, necrotizing enterocolitis, or, rarely, the sequela of a ruptured appendix or Meckel diverticulum. Meconium peritonitis is described in Chapter 91.1 and Chapter 311.2 .

352.1 Acute Primary Peritonitis

Etiology and Epidemiology.

Primary peritonitis usually refers to bacterial infection of the peritoneal cavity without a demonstrable intra-abdominal source. Most cases occur in children with ascites resulting from nephrotic syndrome or cirrhosis. Rarely, it may occur in previously healthy children. Most frequently, isolated bacteria include pneumococci, group A streptococci, enterococci, staphylococci, and gram-negative enteric bacteria, especially *Escherichia coli* and *Klebsiella pneumoniae.* The genders are affected equally; most cases occur before 6 yr of age. *Mycobacterium tuberculosis* and *M. bovis* are rare causes of peritonitis.

Clinical Manifestations.

Onset may be insidious or rapid and is characterized by fever, abdominal pain, vomiting, diarrhea, and a “toxic appearance.” Hypotension and tachycardia are common along with shallow, rapid respirations because of discomfort associated with breathing. Abdominal palpation may demonstrate rebound tenderness and rigidity. Bowel sounds are hypoactive or absent. The prior use of corticosteroids may diminish the clinical expression of peritonitis and delay diagnosis.

Diagnosis and Treatment.

Leukocytosis (on complete blood count) with a marked predominance of polymorphonuclear cells is common, although the level of the white cell count may be affected by pre-existing hypersplenism in patients with cirrhosis. Proteinuria is present in subjects with nephrotic syndrome. Roentgenographic examination of the abdomen reveals dilatation of the large and small intestines, with increased separation of loops secondary to bowel wall thickening. Distinguishing primary peritonitis from appendicitis may be impossible in patients without a history of nephrotic syndrome or cirrhosis; accordingly, the diagnosis of primary peritonitis is made only at laparotomy. In a child with known renal or hepatic disease and ascites, the presence of peritoneal signs should prompt a diagnostic paracentesis. Infected fluid usually reveals a white cell count of 250 cells/mm^3 or greater, with more than 50% polymorphonuclear cells.

Other peritoneal fluid findings suggestive of primary peritonitis include a pH less than 7.35, arterial-ascitic fluid pH gradient greater than 0.1, and elevated lactate. Gram stain of the ascitic fluid characteristically reveals a single species of gram-positive or, less often, gram-negative bacteria. The presence of mixed bacterial flora on ascitic fluid examination or free air on abdominal roentgenogram in children with presumed primary peritonitis mandates laparotomy to localize a perforation as a likely intra-abdominal source of the infection. Inoculation of ascitic fluid obtained at paracentesis directly into blood culture bottles will increase the yield of positive cultures. Parenteral antibiotic therapy with cefotaxime and an aminoglycoside should be started promptly, with subsequent changes dependent on sensitivity testing (vancomycin for resistant pneumococci). Therapy should be continued for 10–14 days.

Culture-negative neutrocytic ascites is a variant of primary peritonitis with a cell count of 500 cells/mm^3 , a negative culture, no intra-abdominal source of infection, and no prior treatment with antibiotic. It should be treated in a similar manner as primary peritonitis.

Nohr CW, Marshall BG: Primary peritonitis in children. *Can J Surg* 1984;27:179.

352.2 Acute Secondary Peritonitis

This is most often due to the entry of enteric bacteria into the peritoneal cavity through a necrotic defect in the wall of the intestines or other viscus as a result of obstruction or infarction or after rupture of an intra-abdominal visceral abscess. It commonly follows perforation of the appendix. Other gastrointestinal causes include incarcerated hernias, rupture of a Meckel diverticulum, midgut volvulus, intussusception, hemolytic uremic syndrome, peptic ulceration, inflammatory bowel disease, necrotizing cholecystitis, necrotizing enterocolitis, typhlitis, and traumatic perforation. Peritonitis in the neonatal period most often occurs as a complication of necrotizing enterocolitis but may be associated with meconium ileus or spontaneous (or indomethacin-induced) rupture of the stomach or intestines. In postpubertal females, bacteria from the genital tract *(Neisseria gonorrhoeae, Chlamydia trachomatis)* may gain access to the peritoneal cavity via the fallopian tubes, causing secondary peritonitis. The presence of a foreign body, such as a ventriculoperitoneal catheter or peritoneal dialysis catheter, can predispose to peritonitis, with skin microorganisms, such as *Staphylococcus epidermidis, S. aureus,* and *Candida albicans,* contaminating the shunt.

Clinical Manifestations.

Similar to primary peritonitis, characteristic symptoms include fever (39.5°C or more), diffuse abdominal pain, nausea, and vomiting. Physical findings of peritoneal inflammation include rebound tenderness, abdominal wall rigidity, a paucity of body motion (lying still), and decreased or absent bowel sounds from a paralytic ileus. Massive exudation of fluid into the peritoneal cavity, along with the systemic release of vasodilatory substances, can lead to the rapid development of shock. A “toxic appearance,” irritability, and restlessness are common. Basilar atelectasis as well as intrapulmonary shunting may develop with progression to acute respiratory distress syndrome.

Laboratory studies reveal a peripheral white cell count greater than 12,000 cells/mm^3 with a marked predominance of polymorphonuclear forms. Roentgenograms of the abdomen may reveal free air in the peritoneal cavity, evidence of ileus or obstruction, peritoneal fluid, and obliteration of the psoas shadow.

Treatment.

Aggressive fluid resuscitation and support of cardiovascular function should begin immediately. Stabilization of the patient before surgical intervention is mandatory. Antibiotic therapy must provide coverage for those organisms that predominate at the site of presumed origin of the infection. For perforation of the lower gastrointestinal tract, a regimen of ampicillin, gentamicin, and clindamycin will adequately address infection by *E. coli, Klebsiella,* and *Bacteroides* species, and enterococci. Alternative therapy could include ticarcillin-clavulanic acid and an aminoglycoside. Surgery to repair a perforated viscus should proceed after the patient is stabilized and antibiotic therapy initiated. Intraoperative peritoneal fluid

cultures will indicate whether a change in the antibiotic regimen is warranted.

352.3 Acute Secondary Localized Peritonitis (Peritoneal Abscess)

Etiology.

Intra-abdominal abscesses may develop within visceral intra-abdominal organs (hepatic, splenic, renal, pancreatic, tubo-ovarian abscesses) or in the interintestinal, periappendiceal, subdiaphragmatic, subhepatic, pelvic, and retroperitoneal spaces. Most commonly, periappendiceal and pelvic abscesses arise from a perforation of the appendix. Transmural inflammation with fistula formation may result in intra-abdominal abscess formation in children with Crohn disease.

Clinical Manifestations.

Prolonged fever, anorexia, vomiting, and lassitude are suggestive of the development of an intra-abdominal abscess. The peripheral white cell count is elevated, as is the erythrocyte sedimentation rate. With an appendiceal abscess, there is localized tenderness and a palpable mass in the right lower quadrant.

A pelvic abscess is suggested by abdominal distention, rectal tenesmus with or without the passage of small-volume mucous stools, and bladder irritability. Rectal examination may reveal a tender mass anteriorly. Subphrenic gas collection, basal atelectasis, elevated hemidiaphragm, and pleural effusion may be present with a subdiaphragmatic abscess. Psoas abscess can develop from extension of infection from a retroperitoneal appendicitis, Crohn disease, or a perirenal or intrarenal abscess. Abdominal findings may be minimal, and presentation may include a limp, hip pain, and fever. Both ultrasound examination and computed tomography (CT) scanning can be used to localize intra-abdominal abscesses. Gallium scanning is usually not needed.

Treatment.

An abscess should be drained and appropriate antibiotic therapy provided. Drainage may be performed under radiologic control (ultrasonogram or CT guidance) and an indwelling drainage catheter left in place. Initial broad-spectrum antibiotic coverage with ampicillin, gentamicin, and clindamycin should be started and can be modified depending on the results of sensitivity testing. The treatment of appendiceal rupture complicated by abscess formation may be problematic because intestinal phlegmon formation can make surgical resection more difficult. Intensive antibiotic therapy for 4–6 wk followed by an interval appendectomy is often the treatment course followed.

Chapter 353 - Diaphragmatic Hernia

Gary E. Hartman

Herniation of abdominal contents into the thoracic cavity may occur as a result of a congenital or traumatic defect in the diaphragm. Symptomatology and prognosis depend on the location of the defect and associated anomalies. The defect may be at the esophageal hiatus (hiatal), adjacent to the hiatus (paraesophageal), retrosternal (Morgagni), or posterolateral (Bochdalek). Although all these defects are congenital, the term congenital diaphragmatic hernia (CDH) has become synonymous with herniation through the posterolateral foramen of Bochdalek. These lesions usually present with profound respiratory distress in the neonatal period, may be associated with anomalies of other organ systems, and have a significant (40–50%) mortality.

Epidemiology.

Reports of the incidence of CDH vary from 1 in 5,000 live births to 1 in 2,000 if stillbirths are included. Defects are more common on the left (70–85%) and are occasionally (5%) bilateral. Malrotation of the intestine and some degree of pulmonary hypoplasia occur in virtually all cases and are considered components of the lesion and not associated anomalies. True associated anomalies have been recognized in 20–30% and include central nervous system lesions, esophageal atresia, omphalocele, cardiovascular lesions, and recognized syndromes. In addition to trisomy 21, the lethal syndromes of trisomy 13, trisomy 18, Fryn, Brachmann–de Lange, and Pallister-Killian have been described. Tetrasomy 12p mosaicism (Pallister-Killian syndrome) may have a normal peripheral blood karyotype as a result of infrequent involvement of lymphocytes. This lethal syndrome can be diagnosed by karyotype from amniocentesis or neonatal bone marrow or fibroblasts. Reports of occurrence of CDH in twins, siblings, and offspring are sporadic. An autosomal recessive inheritance mode has been suggested in families with complete agenesis of the diaphragm.

Etiology.

Separation of the developing thoracic and abdominal cavities is accomplished by closure of the posterolateral pleuroperitoneal canals during the 8th wk of gestation. Failure of this canal to close has been the postulated mechanism for the development of congenital posterolateral diaphragmatic hernia. This may be the mechanism in patients with a small diaphragmatic defect. Production of unilateral or bilateral diaphragmatic defects in experimental animals by in utero drug exposure suggests an additional mechanism that may explain larger defects. Portions of the diaphragm and the pulmonary parenchyma arise from the developing thoracic mesenchyme, which, if disrupted, may explain the absence of the major portion of a hemidiaphragm and the severe pulmonary hypoplasia that usually accompanies such a large defect.

Pathology.

The pathologic changes in infants with congenital diaphragmatic hernia are not limited to the diaphragm. The diaphragmatic defect may be small and slitlike or include the entire hemidiaphragm. Both lungs are small compared with those of age- and weight-matched controls, with the lung on the side of the defect more severely affected. There is a decrease in the number of alveoli and bronchial generations. The pulmonary vasculature is abnormal, with a decrease in volume and marked increase in muscular mass in the arterioles. Although there is some evidence that the pulmonary abnormalities are due to compression by the intrathoracic abdominal viscera, it is not accepted that physical compression is the sole or primary cause.

Clinical Manifestations.

Although many cases are identified by prenatal ultrasonography, the majority of infants with CDH experience severe respiratory distress within the first hours of life. A small group will present beyond the neonatal period. Patients with a delayed presentation may experience vomiting as a result of intestinal obstruction or mild respiratory symptoms. Delayed presentation of right diaphragmatic hernia after a documented episode of group B streptococcal sepsis is well described. Occasionally, incarceration of the intestine will proceed to ischemia with sepsis and cardiorespiratory collapse. Unrecognized diaphragmatic hernia is a rare cause of sudden death in infants and toddlers.

Diagnosis.

Prenatal diagnosis by ultrasonography is common. Careful evaluation for other anomalies should include echocardiography and amniocentesis. Occasionally, a fetus with ultrasonographic diagnosis in utero will have no abnormality on postnatal x-ray film. Parents with the ultrasonographic diagnosis of diaphragmatic hernia must be counseled carefully by a multidisciplinary group with significant experience with this condition if unnecessary terminations and unrealistic expectations are to be avoided.

After birth most infants with diaphragmatic hernia will experience severe respiratory collapse within the first 24?hr. The absence of breath sounds and shift of heart sounds common to CDH and pneumothorax will be accompanied by a scaphoid abdomen in infants with CDH. Thoracentesis or tube thoracostomy should be withheld if CDH is considered a possibility. Chest roentgenogram is usually diagnostic (Fig. 353–1). The lateral view frequently demonstrates the intestine

passing through the posterior portion of the diaphragm. Occasionally, congenital cystic lesions of the lung may produce a similar radiographic appearance. Differentiation from diaphragmatic hernia may be accomplished by postnatal ultrasonography or injection of contrast into the stomach or umbilical artery catheter to identify intestine above the diaphragm. In older children with atypical symptoms, contrast studies of the gastrointestinal tract are usually required. Ultrasonography and fluoroscopy are helpful in distinguishing eventration from true hernia, and computed tomography may be necessary to exclude pneumatoceles or complicated effusions.

Treatment.

The availability of extracorporeal membrane oxygenation (ECMO) and the utility of preoperative stabilization have been the major stimuli to aggressive therapy (Chapter 90.7). Diaphragmatic hernia was once considered a surgical emergency. Recognition of the role of pulmonary hypertension in addition to pulmonary hypoplasia and the adverse effects of operative repair on pulmonary function has caused a policy of delayed repair. The postnatal mass effect of the herniated viscera

Figure 353-1 Congenital diaphragmatic hernia. *A*, Film exposed shortly after birth: Distortion of shadow of the left leaf of the diaphragm with huge, masslike density in left hemithorax displacing the heart to the right. *B*, Film exposed about 20?min after *A*. As the result of swallowed air, coils of air-filled small bowel are now demonstrated in the left hemithorax. The esophagus is outlined by swallowed contrast material. Operative correction was attempted because of extreme dyspnea. Infant died 5.5?hr after birth.

is a minor factor in the cardiorespiratory compromise compared with the pulmonary hypertension and hypoplasia.

Initial resuscitation has traditionally consisted of attempted stabilization with sedation and paralysis and modest hyperventilation (partial pressure of carbon dioxide of 25–30?mm Hg). Permissive hypercapnia with gentle ventilation has been proposed by a number of centers with reports of equal or improved survival and decreased incidence of need for ECMO. Volume resuscitation, dopamine, and bicarbonate (to maintain pH > 7.50) may also be helpful. If the infant stabilizes and demonstrates stable pulmonary vascular resistance without significant right-to-left shunting, repair of the diaphragm is performed at 24–72?hr of age. If stabilization is not possible or significant shunting persists, most infants will require ECMO support. Vasoactive drugs (dopamine) and inhaled nitric oxide may provide some improvement but have been disappointing as definitive therapy for the pulmonary hypertension associated with diaphragmatic hernia. Dipyridamole has been reported to facilitate weaning from inhaled nitric oxide in refractory pulmonary hypertension. Surfactant administration has also been shown to produce a transient improvement in oxygenation in some infants with CDH.

ECMO with paralysis and nasogastric suction may produce a dramatic reduction of the volume of herniated viscera. The duration of ECMO for neonates with diaphragmatic hernia is significantly longer (7–14 days) than for those with persistent fetal circulation or meconium aspiration and may last up to 2–4 wk. Timing of repair of the diaphragm on ECMO is controversial; some centers prefer early repair to allow a greater duration of postrepair ECMO, whereas many centers defer repair until the infant has demonstrated the ability to tolerate weaning from ECMO. In either case, recurrence of pulmonary hypertension carries a high mortality, and weaning from ECMO support should be cautious. If the patient cannot be weaned from ECMO after repair, options include discontinuing support or therapies such as nitric oxide or lung transplantation. High-frequency jet ventilation and oscillatory ventilation have had limited success in newborns with CDH.

The abdominal surgical approach is favored because the accompanying malrotation may be addressed if necessary, and the abdominal wall may be left open with skin only closed or a Silastic pouch applied if abdominal pressure is considered excessive. Synthetic patch (polytetrafluoroethylene) is now preferred over autologous muscle transfer or tight primary closure for large defects.

The appreciation of the compressive effects of the herniated viscera and the availability of prenatal diagnosis suggested the utility of in utero measures directed at potentially reversing the pulmonary hypoplasia and, it is hoped, the pulmonary vascular changes. Prenatal treatment with glucocorticoids has stimulated pulmonary maturity in experimental animals with diaphragmatic hernia. In utero reduction of the herniated viscera also has been successsfully performed. In experimental animals, occluding the trachea in utero enhances lung growth by preventing lung fluid egress. Randomized trials comparing in utero repair or tracheal occlusion with standard postnatal therapy has been discontinued because there was no difference in mortality or morbidity between treatment groups.

Prognosis.

Studies of infants with CDH identified in utero report lower survival (27–55%) than noted in reports limited to live births (42–75%). It appears that many fetuses with the diagnosis of CDH who do not survive pregnancy die as a result of elective termination. The incidence of spontaneous fetal demise among fetuses diagnosed as having CDH appears to be 7–10%. Of those surviving to delivery, survival appears to range from 42–75% despite current modalities including ECMO. Factors associated with a poor prognosis include associated major anomaly, symptoms before 24?hr of age, severe pulmonary hypoplasia and herniation to the contralateral lung, distress severe enough to require ECMO, and delivery in a nontertiary center. Initial attempts at intrauterine repair were associated with a low survival (29%), although current results are more encouraging.

A significant number of survivors are being identified with serious sequelae, primarily pulmonary, neurologic, and growth retardation. These long-term sequelae are probably the result of survival of infants with severe pulmonary compromise. Ten to 20% of CDH survivors require oxygen therapy at discharge.

Studies have documented abnormalities of pulmonary function in the perioperative period and years after repair. Survivors of CDH repair studied at 6–11 yr of age demonstrate significant decreases in forced expiratory flow at 50% of vital capacity and peak expiratory flow. The lung on the affected side is larger than predicted, suggesting hyperinflation, and has reduced perfusion. These patients had undergone repair before the availability of ECMO. In studies of neonatal pulmonary function,

neonates with CDH requiring ECMO demonstrate significantly decreased compliance, dynamic compliance, and tidal volume when compared with those not requiring ECMO. After repair, infants with CDH also have evidence of reactive airway disease. Survivors of CDH have evidence of restrictive lung disease and airway reactivity, which are related to the severity of their initial respiratory failure.

Neurologic abnormalities have been identified in survivors of CDH. The incidence of neurologic abnormalities is higher in those infants requiring ECMO (67% vs 24%). The abnormalities are similar to those seen in neonates treated with ECMO for other diagnoses and include transient and permanent developmental delay, abnormal hearing or vision, seizures, and abnormal CT. The majority of neurologic abnormalities are classified as mild or moderate.

Growth and nutrition are compromised in CDH survivors who require ECMO. Forty to 50% are at less than the 5th percentile for weight at 2 yr of age. Weight-to-length ratio is less than the 5th percentile in 40% of survivors at 1 yr and at the 21st percentile at 2 yr. Nearly all ECMO survivors demonstrate clinical evidence of gastroesophageal reflux, and 20% or more have required fundoplication. Dilation of the esophagus with altered motility that resolves during the 1 yr of life has been correlated with a prenatal history of polyhydramnios.

Other long-term problems occurring in this population include pectus excavatum, scoliosis, fixed pulmonary hypertension, and recurrent herniation. Recurrent hernia formation is common in newborns with large defects requiring synthetic patch repair. Reherniation, which occurs within the 1st yr, has been reported in 20–40% of those requiring patch repair.

Survivors of CDH repair, particularly those requiring ECMO support, have a variety of long-term abnormalities that appear to improve with time but require close monitoring and multidisciplinary support.

353.1 Foramen of Morgagni Hernia

The anteromedial diaphragmatic defect through the foramen of Morgagni accounts for 2% or less of diaphragmatic hernias. The transverse colon or small intestine is usually contained in the hernia sac. Symptoms are gastrointestinal and typically occur beyond the neonatal period. Repair is recommended for all patients and can be accomplished by laparotomy.

353.2 Paraesophageal Hernia

Paraesophageal hernia is differentiated from hiatal hernia in that the gastroesophageal junction is in the normal location. The herniation of the stomach alongside or adjacent to the gastroesophageal junction is prone to incarceration with strangulation and perforation. This unusual diaphragmatic hernia should be repaired promptly after identification.

353.3 Eventration

Eventration of the diaphragm consists of a thinned diaphragmatic muscle producing elevation of the entire hemidiaphragm or, more commonly, the anterior aspect of the hemidiaphragm. Most eventrations are asymptomatic and do not require repair. Large or symptomatic eventrations may be repaired by plication through an abdominal or a thoracic approach.

Chapter 354 - Epigastric Hernia

Gary E. Hartman

Epigastric hernias are defects in the linea alba between the xyphoid and the umbilicus. They are uncommon in childhood, constituting less than 1% of hernias requiring operation. Similar defects below the umbilicus are even more uncommon. These hernias usually contain preperitoneal fat and rarely cause symptoms. They may appear as an intermittent bulge or a midline mass if the fat is incarcerated. Herniation of intestine or other

viscera is extremely rare. Repair is indicated for symptomatic hernias or for diagnosis in the case of a mass. Treatment of asymptomatic hernias of the linea alba is less clear. Some believe that many will resolve spontaneously and discourage elective repair. Others believe that they never resolve and will eventually require repair. Abdominal symptoms other than local pain and tenderness should prompt further diagnostic study rather than repair of the epigastric hernia.

354.1 Incisional Hernia

Hernia formation at the site of a previous laparotomy is uncommon in childhood. Factors associated with an increased risk of incisional hernia include increased intra-abdominal pressure, wound infection, and midline incision. Transverse abdominal incisions are favored because of their increased strength and blood supply, which reduce the likelihood of wound infection and incisional hernia. Although most incisional hernias will require repair, operation should be deferred until the child is in optimal medical condition. Some incisional hernias will resolve, especially those occurring in infants. Some recommend elastic bandaging to discourage enlargement of the hernia and to promote spontaneous healing. Newborns with abdominal wall defects represent the largest group of children with incisional hernias. Initial management should be conservative, with repair deferred until about 1 yr of age. Incarceration is very uncommon but is an indication for prompt repair.

Part 18 - The Respiratory System

Section 1 - *Development and Function*

Chapter 355 - Development of the Respiratory System

Gabriel G. Haddad
J. Julio Pérez Fontán

The development of the respiratory system encompasses three distinct processes: morphogenesis or formation of all the necessary structures, adaptation to postnatal atmospheric breathing, and dimensional growth. The first two processes take place primarily before or shortly after birth of an infant. Growth, in contrast, continues after birth at a pace that is generally dictated by the functional needs of the other growing organs and metabolic activity of the child. The effects of an injury to the respiratory system depend, therefore, not only on the severity and chronicity of the injury but also on the timing of the injury in relation to the developmental timetable of the lungs. Insults occurring during morphogenesis, for instance, tend to produce severe and irreversible disruptions of respiratory structure and function, often incompatible with survival. In contrast, injuries that take place during later stages of lung growth are frequently reversible and, if not, can be compensated for by the growth process itself.

Prenatal Development: Morphogenesis.

In humans and other mammals, the morphogenesis of the respiratory system is divided into five periods (Fig. 355–1). The first, or *embryonic period*, begins at approximately 4 wk of gestation, when the primitive airways appear as a ventral outpouching on the endodermal epithelium of the foregut. This outpouching divides almost immediately into two main stem bronchial buds, which burrow rapidly into the mesenchyme separating the foregut from the coelomic cavity. The bronchial buds start to branch, first by monopodal outgrowth (secondary branches grow out of a main branch) and then by asymmetric dichotomy (two secondary branches originate from one main branch).

The peribronchial mesenchyme or *splanchnopleura* plays an essential role in shaping the lungs during the embryonic period. Close contact between this mesenchyme and the epithelium of the bronchial buds is essential for the continued branching of the airways. Although the factors that promote bronchial division are not fully identified, steroid-induced secretion of growth factors by the mesenchymal fibroblasts, specific interactions with acellular components of the mesenchyme, and even direct molecular communications between fibroblasts and endodermal cells across gaps in the basal membrane may be signaling mechanisms. The interactions between mesenchyme and the bronchial bud endoderm are organ specific.

The pulmonary vasculature is a mesenchymal derivative. Soon after their appearance, the bronchial buds are surrounded by a vascular plexus, which originates from the aorta and drains into the major somatic veins. This vascular plexus connects with the pulmonary artery and veins to complete the pulmonary circulation at the 7th wk of gestation but retains some aortic connections that form the bronchial arteries. All the supporting structures of the lungs, including the pleura, the septal network of the lungs, and the smooth muscle, cartilage, and connective covers of the airways, originate from the mesenchyme.

Toward the 6th wk of gestation, at the beginning of the second or *pseudoglandular period*, the lungs resemble an exocrine gland with a thick stroma crossed by narrow ducts lined by an epithelium of tall cells that almost fill the lumen. The major airways are already present and are in close association with pulmonary arteries and veins. The trachea and the foregut are now separated after the progressive fusion of epithelial ridges growing from the primitive airway. The incomplete fusion of these ridges results in a **tracheoesophageal fistula,** a common congenital malformation. During the pseudoglandular period, the airways continue to branch until the entire conducting airway system is formed, including the primitive bronchioles that eventually give rise to the air-exchanging portions of the lungs. Simultaneously, the pluripotential cells that line the airways differentiate, starting from the trachea and main bronchi. They soon form a thinner, pseudostratified epithelium containing ciliated, secretory (Clara), globular, and neuroendocrine (Kulchitsky) cells of neuroectodermal origin. Mucus glands, cartilage, and smooth muscle can be easily distinguished by the 16th wk of gestation.

The diaphragm is formed during this period. Its central tendon originates from the transverse septum, a plate of mesodermal tissue located between the pericardium and the stalk of the yolk sac. Its lateral portions are formed by the pleuroperitoneal folds, which grow from the body wall until they fuse with the esophageal mesentery and the transverse septum. The fusion eliminates the communication between thorax and abdomen and establishes a barrier to the caudal growth of the lungs. Its failure, usually on the left side, causes the **congenital diaphragmatic hernia of Bochdalek** (see Chapter 353). This defect allows the abdominal organs to enter the primitive

pleural cavity and interferes with airway and pulmonary vascular branching. The result is severe hypoplasia of the lung, particularly on the side of the hernia.

During the third or *canalicular period*, between the 16th and 26–28th wk of gestation, epithelial growth predominates over mesenchymal growth. As a result, the bronchial tree develops a more tubular appearance, whereas its distal regions subdivide further to lay the structural foundations of the pulmonary acinus. The epithelial cells in these regions become more cuboidal and start to express some of the antigen markers that characterize cells as type II pneumocytes. Some cells become flatter and can be identified as potential type I pneumocytes by the presence of a sparse endoplasmic reticulum and abundant cytoplasmic glycogen. The capillaries contained in the distal bronchial mesenchyme form a denser network and grow closer to the

Figure 355-1 Development of various pulmonary structures during the five stages of prenatal lung development (see text).

potential air spaces, making limited gas exchange possible by 22 wk of gestation.

Between the 26–28th wk of gestation, lung morphogenesis enters its *saccular period*, during which the terminal airways continue to widen and form cylindrical structures known as saccules. Initially smooth, the internal surface of the saccules soon develops ridges or secondary crests, which originate as folds of the epithelium and peribronchial mesenchyme and contain a double capillary layer. The distance between the capillaries and the potential air spaces narrows further until eventually only a thin basal membrane separates them.

Exactly when the saccular period ends and the *alveolar period* begins depends on the definition of what constitutes an alveolus. Formation of alveoli before birth is not a requisite for survival. In the human fetus, the saccular septation initiated with the appearance of the secondary crests continues at a rapid rate so that multifaceted structures analogous to the alveoli of the mature lung can be seen at 32 wk of gestation. There is substantial evidence that the timing and progression of alveolar septation is under endocrine regulation. Thyroid hormones stimulate septation, whereas glucocorticoids impair it in a fashion that, at least in the rat, can be irrevocable (even though they accelerate the thinning of the alveolar capillary membranes). Alveolarization is also influenced by physical stimuli. Both the stretch by the liquid contained in the fetal lung and the periodic distention provided by the action of the respiratory muscles during fetal breathing, for instance, appear to be necessary for the development of the acini. Their absence when the lungs or chest are compressed (as in the case of a diaphragmatic hernia or oligohydramnios) or when fetal breathing is abolished (e.g., by spinal cord lesions) results in **pulmonary hypoplasia** with reduced numbers of alveoli.

A number of gene families have been identified as being essential for development. The homeodomain or homeobox (hox) gene family is critical in mammalian organ development, including that of the respiratory system. Hoxa-1,2,3,5, and Hoxb-3,4,6,7,8 mRNA transcripts have been identified using molecular biologic techniques in branching regions of the developing mouse lung. These *Hox* genes were differentially expressed in time and space in early lung development, indicating that they play a role in the differentiation, maturation, and proliferation of various lung cells throughout the various phases of lung development. Hoxa-2 seems to be tied to a proximal role in branching and differentiation, whereas Hoxb-6 is involved in distal airway branching. Also of importance is the fact that the expression of some of these genes is controlled by retinoic acid. This may be related to a possible therapeutic role of retinoic acid at later stages of lung development or in injured lungs.

Adaptation to Air Breathing.

The transition from placental dependence to autonomous gas exchange requires adaptive changes in the lungs. These changes include the production of surfactant in the alveoli, the transformation of the lung from a secretory to a gas-exchanging organ, and the establishment of parallel pulmonary and systemic circulations.

As soon as the newborn infant takes the first breath of air, an air-liquid interface becomes established inside the lungs. Unless the surface tension generated at this interface is reduced, the walls of the air spaces would tend to stick together and collapse, threatening the geometric stability of the lungs. The pulmonary surfactant makes such a reduction possible by forming a hydrophobic lipid monolayer at the very surface of the liquid film that lines the air spaces (see Chapter 90.3 and Chapter 397). Pulmonary surfactant is a heterogeneous mixture of phospholipids and proteins secreted into the saccular or alveolar subphase by the type II pneumocytes. Its presence is first recognized in characteristic secretory organelles known as lamellar bodies as early as the 24th wk of gestation. However, surfactant lipids, of which the most abundant is phosphatidylcholine, are not detectable in the amniotic fluid until the 30th wk of gestation, suggesting that there is a chronologic gap between surfactant synthesis and secretion. Labor probably shortens this gap because phospholipids are consistently found in the air spaces of infants born before the 30th wk of gestation. Three apoproteins (SP-A, SP-B, SP-C) identified in pulmonary surfactant (a fourth lectin-like glycoprotein, SP-D, has been isolated, but its function and regulation are still poorly understood) promote the spreading of the surfactant layer and are therefore essential for the effective reduction of surface tension. Apoproteins also appear to be important for the reuptake and recycling of surfactant products and for the formation of tubular myelin (the structures in which surfactant is stored in the liquid subphase).

Surfactant apoproteins and phospholipids share some, but not all, of their regulatory influences. Glucocorticoids, for instance, increase the synthesis of both apoproteins and lipids; accordingly, their prenatal administration has been used to prevent the respiratory distress syndrome associated with prematurity. Because many actions of the steroids involve direct stimulation of response elements in apoprotein and phospholipid enzyme genes and therefore require messenger RNA production, sufficient time must elapse between steroid administration and birth. Thyroid hormones also enhance the synthesis of phospholipids by a receptor-mediated mechanism, but, unlike the glucocorticoids, have little or no effect on surfactant apoprotein synthesis. Conversely, ß-adrenergic agonists and other agents that raise cellular cyclic adenosine monophosphate content increase apoprotein synthesis and phosphatidylcholine secretion into the air spaces but have no effect on phospholipid synthesis. Insulin, hyperglycemia, ketosis, and androgens may have negative effects

on the production of surfactant proteins and phospholipids, thus explaining the high incidence of respiratory distress syndrome in infants of diabetic mothers and the slight maturational delay of the lungs of male fetuses compared with female fetuses.

Surfactant proteins and lipids also may play an important role in lung immunity, although the molecular details are not known. Surfactant proteins A and D are lectins (bind to carbohydrates) and belong to the collectins family of genes. These proteins, present in the serum and lungs, stimulate phagocytosis and chemotaxis, produce reactive oxygen species, and regulate the production and release of cytokines by immune cells. Alternatively, surfactant lipids can suppress immunity. It is possible that the ratio between surfactant lipids and proteins is important in regulating the immune status of the lungs. This may be critical in premature infants and in newborns who lack

surfactant proteins; knockout mice with SP-A deficiency have a major problem with infections.

The fetal lung is a secretory organ. Throughout gestation, a Cl^-, K^+ -, and H^+ -enriched fluid is produced in its peripheral air spaces with the help of a Cl^- pump. The presence of this fluid appears to be important for the development of the acinus because chronic drainage of the trachea in experimental animals results in lung hypoplasia. Fluid secretion, however, is incompatible with air breathing. Accordingly, and in preparation for birth, lung fluid production decreases slowly at the end of gestation. This decrease, which is accelerated by the beginning of labor, denotes a transformation in the ion transfer activities of the pulmonary epithelium from Cl^- (and water) secretion to Na^+ (and water) absorption. In experimental animals, such a transformation can be precipitated by the administration of ß-adrenergic agonists at doses that result in serum levels comparable to those found during labor. Stimulation of ß-adrenergic receptors is not the only labor-related signal because fluid clearance in the fetal lung is delayed by the Na^+ channel blocker amiloride but not by ß-blockers. After birth, the still substantial amount of fluid left in the lungs is absorbed over several hours into the circulation either directly through pulmonary vessels or indirectly through an already very effective lymphatic system. The cellular elements responsible for fluid secretion and absorption in the lungs are not fully identified. It is obvious that a mature alveolar epithelium is not essential for fluid secretion, which is already taking place before alveoli or even saccules exist. Alveolar cells, in contrast, probably play a protagonistic role in fluid absorption. Type II pneumocytes may be involved because they cover a larger portion of the air space surface in the newborn than in the adult and their metabolic machinery appears to be particularly well adapted to active ion transport.

A number of transporters and channels that are important to water and solute transport in early life have been cloned and identified in the past decade. Most prominent has been the epithelial sodium channel (ENaC). It is the amiloride-sensitive and apical channel that is responsible for sodium and water absorption in the luminal surface of the airways and renal tubular cells. This channel seems to be critical in early life.

At birth, the pulmonary circulation changes from a high-resistance to a low-resistance system and, as a consequence, pulmonary blood flow becomes capable of accommodating systemic venous return. The change in resistance is brought about by the combined effects of the mechanical forces applied on the pulmonary vascular walls by the expanding lung tissue and the relaxation of the pulmonary arterial smooth muscle caused by the increased alveolar concentrations of oxygen and probably by endogenous release of vasodilators. The subsequent closure of the foramen ovale and the ductus arteriosus completely separates the pulmonary from the systemic circulation. Arterial oxygen tension then rises sharply and becomes homogeneous throughout the body. Pulmonary vascular resistance continues to decrease gradually during the first few weeks after birth through a process of structural remodeling of the pulmonary vessel musculature.

Postnatal Development.

The postnatal development of the lungs can be divided into two phases depending on the relative rates of development of the various components of the lungs. During the first phase, which extends to the first 18 mo after birth, there is a disproportionate increase in the surface and volume of the compartments involved in gas exchange. Capillary volume increases more rapidly than air space volume, which, in turn, increases more rapidly than solid tissue volume. These changes are accomplished primarily through a process of alveolar septation. This process is particularly active during early infancy and may reach completion within the first 2 yr of life. The configuration of the air spaces becomes progressively more complex, not only because of the development of new septa but also because of the lengthening and folding of the existing alveolar structures. Soon after birth, the double capillary system contained in the alveolar septa of the fetus fuses into one single, denser system. At the same time, new arterial and venous branches develop within the circulatory system of the acinus and muscle starts to appear in the medial layer of the intra-acinar arteries.

During the second phase, all compartments grow more proportionately to each other. Although new alveoli may still be formed, the majority of the growth occurs through an increase in the volume of existing alveoli. Alveolar and capillary surfaces expand in parallel with somatic growth. As a result, taller individuals tend to have larger lungs. However, the final size of the lungs and, ultimately, the dimensions of the individual constituents of the acinus are also influenced by factors such as the subject's level of activity and prevailing state of oxygenation (altitude), which allow for a better adaptation of lung structure and function. The same factors are probably operative in the compensatory responses to pulmonary disease and injury.

Chapter 356 - Regulation of Respiration

Gabriel G. Haddad

Pediatricians need to be familiar with the general principles of the regulation of respiration because (1) clinical situations involving one or more elements of the respiratory control system are prevalent, especially in critically ill patients (e.g., apnea, upper airway obstruction, severe asthma, hypoventilation, and heart failure, or hypoxemia from various causes); (2) transition from fetal to neonatal life is an extremely complex process during which there are major changes in almost every aspect of respiratory control; and (3) understanding of the neural control of respiration is likely to increase significantly from advances in understanding brain function in general.

The Respiratory Control System is a Negative Feedback System with a Central Controller.

The overall aim of the respiratory feedback system is to keep blood gas homeostasis in a normal range in the most economical way, from an energy consumption and mechanical standpoint. The term *negative* in this concept refers to the fact that the controller attempts to rectify the deviation from normality. If CO_2 increases, for example as a result of airway obstruction, the output of the controller is increased in an attempt to increase alveolar ventilation and decrease CO_2 . To accomplish this, the feedback system makes use of both an afferent limb and an efferent limb. The afferent limb is made up of tissues (e.g., the airways) that have receptor endings and can send information to the central controller about certain functional parameters, such as the magnitude of stretch of the airways. The carotid bodies that inform the central controller of the status of O_2 and pH represent another important part of the

afferent system. Both airway and carotid body sensors have a way to compare signals, the inherent set point signal and the real actual one, note differences, and translate these differences into information (e.g., a decrease or increase in action potential volleys) to the central nervous system (CNS). The efferent loop is the part of the feedback system that is responsible for the execution of the decision made centrally to increase or decrease central respiratory output (i.e., increase or decrease respiratory muscle output). There are many muscles of respiration, the

intercostal muscles and the diaphragm being only two of them. Activity and timing of the airway muscles, as is seen later, are crucial in determining airway resistance and, therefore, the magnitude of ventilation.

The Central Controller Integrates Incoming Afferent Information and Generates and Maintains Respiration.

It is not known in precise mechanistic and cellular terms how and where integration and generation of breathing take place. Two groups of medullary neurons have been considered as potential sites for the initiation of respiration, namely, the nucleus tractus solitarius and the nucleus ambiguus (and retroambiguus). Another area in the medulla (pre-Botzinger complex) has been implicated as a major site for the generation of respiration. This region is essential for the respiratory rhythm generation and could constitute the “sinus node” of respiration. There are neurons in this complex that have pacemaker-like membrane properties. However, the nature of the central respiratory rhythm generator is not yet fully clear. The respiratory controller may be a group of neurons that either form an emergent network or are endogenous or conditional bursters. In the first case, respiratory neurons would not have special properties (e.g., bursting properties) that would make their membrane potential oscillate. This type of a respiratory rhythm generator would *not* be like the sinus node cells of the heart. Rather, the output of the network that they form would oscillate because of the special interconnections and synaptic interactions among these respiratory neurons. In the second case, in a manner similar to that of the heart, the respiratory neurons would have special properties that make individual neurons “burst” or oscillate (pacemaker), even if they are disconnected from any other neurons (endogenous burster). A conditional burster neuron is a neuron that oscillates only when exposed to certain chemicals (e.g., neurotransmitters). It is likely that, independent of the location of the central pattern generator, a respiratory oscillatory output takes place by virtue of the synaptic and cellular-molecular properties of the neurons in all of these locations. This oscillatory output from the brain-stem then drives the phrenic motor neurons in the spinal cord that, in turn, stimulate the diaphragm and other respiratory muscles to contract and move air in the lungs. One issue regarding the activation (or inactivation) of various respiratory muscles is how the central output gets “distributed” on muscles to ensure patency of airways and contraction of the appropriate muscles in order to optimize the work of breathing and lessen the energy needed to move a certain volume of air and ensure alveolar ventilation. This issue is important in some pathologic states during which airway muscle activation may not be well coordinated with chest wall muscle activation, leading to lack of airway patency and inefficient gas exchange.

Afferent Information is Not Necessary for Initiating Respiration but Plays an Important Role in Modulating Breathing.

A multitude of afferent messages converge on the brainstem at any one time. Chemoreceptors and mechanoreceptors in the larynx and upper airways sense stretch, air temperature, and chemical changes over the mucosa and relay this information to the brainstem. Afferent impulses from these areas travel through the superior laryngeal nerve and the 10th cranial (vagus) nerve. The superior laryngeal nerve joins and becomes part of the vagal trunk at the nodose ganglion. Changes in O_2 or CO_2 tensions are sensed at the carotid and aortic bodies, and afferent impulses travel through the carotid and aortic sinus nerves. Thermal or metabolic changes are sensed by skin or mucosal receptors or by hypothalamic neurons and are carried through spinal or central tracts to the brainstem for integrative purposes. Furthermore, afferent information to the brainstem need not be only formulated and sensed by the peripheral nervous system. For example, (1) sensors of CO_2 lie on the ventral surface of the medulla oblongata and therefore feedback about CO_2 levels comes from the brainstem itself and (2) emotions and changes in mood that result from CNS processing in the limbic system influence respiration through pathways connecting higher brain centers to the brainstem.

Afferent information from the peripheral or central nervous system is not a prerequisite for generating and maintaining respiration. When the brainstem and spinal cord are removed from the body and maintained in vitro, rhythmic phrenic activity can be detected and measured for hours. Other experiments in vivo in which several sensory systems are blocked simultaneously indicate that afferent information is not necessary to initiate an inherent respiratory rhythm in brainstem respiratory networks. However, both in vitro and in vivo studies demonstrate that in the absence or elimination of afferent information regarding CO_2 levels, O_2 levels, a wakeful stimulus, and so on, the inherent rhythm of the central generator (respiratory frequency) is slow. Hence, chemoreceptors, temperature receptors, mechanoreceptors, and laryngeal receptors and their afferents play an important part in *modulating* respiration and rhythmic behavior.

The neonate is more exquisitely sensitive to afferent input than is the adult. Laryngeal reflexes are extremely potent in inhibiting respiration in the newborn. Aspiration and stimulation of laryngeal chemoreceptors in premature infants (who lack the ability of a strong cough), especially when these infants are anemic or hypoglycemic or even during normal sleep, can cause life-threatening respiratory events.

Central Integration and Processing in the Brainstem is Hierarchical.

Respiratory muscles can be recruited to perform different tasks at different times. For example, the diaphragm and some abdominal muscles are activated not only during tidal breathing but also during expulsive maneuvers such as coughing and straining. In other conditions, respiratory muscles can be totally inhibited. For example, when delivering a speech, CO_2 responsiveness is decreased substantially because speech muscles are recruited mostly at the expense of other respiratory muscles. Bottle- or breast-feeding in the young is often associated with a reduction in ventilation and a drop in Pa_{O_2} because of partial inhibition of respiratory muscles and breathing efforts. Presented with a number of neurophysiologic signals (representing options about various needs), the central controller responds differently to various stimuli and can enhance or reduce the effect of certain stimuli. Therefore, there is a hierarchy that is used by brainstem networks for determining the response of the respiratory system at any one time.

Changes in the state of consciousness modulate the ability of the brainstem to respond to afferent stimuli. For example, trigeminal afferent impulses are less inhibited by cortical influences during quiet sleep than during rapid eye movement (REM) sleep or wakefulness. Thus, the effect of trigeminal stimulation on respiration is more pronounced in quiet sleep. Similarly, age is important. The response of the brainstem to stimuli varies with maturation and thus with cortical input to brainstem structures.

The idea of hierarchical responses is important also because some of the afferent

inputs to the CNS have a major impact on the respiratory output whereas others do not. For example, many experiments have shown that the laryngeal afferent input into the brainstem is an extraordinarily potent inhibitory reflex to breathing and its effect on the CNS integrator/pattern generator is instantaneous, taking place in a few milliseconds! This

reflex is also very powerful during anesthesia when cortical input to the brainstem is attenuated. This becomes especially important in infants who show frequent apnea and whose apnea gets exaggerated when they are sedated or anesthetized.

Respiratory Muscles and Chest Wall Properties Undergo Postnatal Maturation and Can Fatigue.

Effective ventilation requires *coordinated interaction* between the respiratory muscles of the chest wall (including the diaphragm and intercostals) and those of the upper airway (including the pharynx and the larynx) under various conditions of altered respiratory drive. In infants, a specific sequential pattern of nerve and muscle activation occurs so that some upper airway muscles contract before and during the early part of inspiratory flow: the genioglossus muscle contracts, moving the tongue forward, which prevents pharyngeal obstruction, and the vocal cords abduct, reducing inspiratory laryngeal resistance. Laryngeal muscles also modulate expiratory flow and thus may influence lung volume. Imbalance of pharyngeal and diaphragmatic activities or their responses to chemoreceptor or mechanoreceptor stimulation may contribute to obstructive apnea in infants and children.

Because the *respiratory muscles* are responsible for executing central neural responses and because muscle and chest wall properties change with age in early life, it is likely that neural responses can be influenced by pump properties. Thus, it is important to consider the maturational changes of respiratory muscles and the chest wall. For example, one of the important maturational aspects of respiratory muscles (e.g., in skeletal muscles) is their pattern of innervation. In the adult, one muscle fiber is innervated by one motor neuron. Therefore, if a motor neuron innervates certain muscle fibers (e.g., about 200 muscle fibers in the case of the diaphragm), these fibers do not receive innervation from any other motor neuron. In the newborn, however, each fiber is innervated by two or more motor neurons, and the axons of different motor neurons can synapse on the same muscle fiber, hence the term *polyneuronal innervation*. Synapse elimination takes place postnatally and, in the case of the diaphragm, the adult type of innervation is reached by several weeks of age depending on the animal species. The time course of polyneuronal innervation of the diaphragm in the human newborn is not known.

The neuromuscular junctional folds, postsynaptic membranes, and acetylcholine receptors and metabolism undergo major postnatal maturational changes. The acetylcholine quantal content per end plate potential is lower in the newborn than in the adult rat diaphragm. The newborn diaphragm is also more susceptible to neuromuscular transmission failure than is that of the adult, especially at higher frequencies of stimulation. Whether this is the result of differences in acetylcholine metabolism between the newborn and the adult or is related to the neuromuscular junction itself is not known.

In addition to an increase in cross-sectional area and muscle mass, *muscle fiber types* in the diaphragm change as a function of gestational and postnatal age. It is not known whether human newborn muscles are more oxidative or fatigue resistant than those of the adult. The sarcoplasmic reticulum of the premature diaphragm is, however, underdeveloped compared with that of the adult. This is one major reason for the delay in the release and uptake of calcium, which may have functional significance. The poorly developed sarcoplasmic reticulum in the newborn causes increased contraction and relaxation time in neonatal muscle fibers. This increased relaxation time may be an important factor in impeding blood flow and limiting oxidative metabolism when the muscle is under a load.

The *chest wall* in newborn infants is highly compliant. Because of this and because young infants spend a large proportion of time in REM sleep, during which the intercostal muscles are inhibited, there is little splinting of the chest wall for diaphragmatic action. Therefore, with every breath in supine infants (especially in REM sleep), the chest wall is sucked in paradoxically at a time when the abdomen expands. This creates an additional load on the respiratory system and results in a higher work of breathing per minute ventilation in the infant than in the adult. This may be an important reason for the newborn's susceptibility to muscle fatigue and respiratory failure.

The Newborn Infant and Young Child Respond Differently to Stimuli Compared with the Mature Individual.

The young child and neonate respond to various stimuli in a different way than does the adult. In response to low O_2 , the newborn infant does not sustain an increase in ventilation, and often ventilation decreases to below baseline levels. CO_2 levels do not increase at a time when ventilation is decreasing, suggesting that ventilation is matching metabolic needs. This neonatal response to low O_2 can be considered an intermediate response between those of the fetus and the adult; the fetus shuts off all respiratory efforts in response to O_2 deprivation, and the adult hyperventilates as long as the stimulus is present. The mechanism or mechanisms for the lack of sustained increase in ventilation during hypoxia in the newborn are not well understood. In addition to differences in metabolic rate during hypoxemia among neonates and adults, changes in the mechanical properties of the lung and airways, maturation of carotid chemoreceptors, and alterations in the cellular and membrane properties of central neurons have all been proposed as potential individual or combined mechanisms. It is clinically important that neonatal tissues (especially heart, brain, and kidneys) resist O_2 deprivation and do not injure as easily as those of the adult. These differences between newborn and adult sensitivity to anoxic injury are not well understood but possibly relate to the ability of the newborn cell to metabolize lactate and ketone, to downregulate metabolism during severe O_2 deprivation, and to regulate certain protein synthesis (e.g., heat-shock proteins) differently from the adult.

CO_2 response is also reduced in the young. Whether this is a reflection of an inherent difference in sensitivity or the result of differences in mechanical function is not known and, presumably, is related to both mechanical and central differences.

Although alterations in responsiveness can be secondary to a number of differences between the young and the mature organism, the central neuronal changes with maturation seem especially important. For example, the soma of lumbar and phrenic motor neurons increases with age, and their input resistance (or inverse of membrane conductance) decreases with age. The decrease in input resistance results in major part from the increase in soma size, but other mechanisms, such as a change in the geometry of the dendrites and their outgrowth, a change in the number of ion channels per surface area, and an increase in the number of synapses onto motor neurons, cannot be ruled out. Axonal velocity also increases with age, and action potentials of phrenic and hypoglossal motoneurons decrease in duration. There are also major maturational changes in active cellular properties in some motor neurons or premotor neurons. For example, with increasing postnatal age, neurons in the area of the nucleus tractus solitarius develop cellular properties important for repetitive firing. Changes in neuronal properties could play an important role in the integrative abilities of neuronal cells and, therefore, in their response to stimulation.

Clinical Implications

APNEA (see Chapter 90.2).

Apnea can be defined statistically as the respiratory pause that exceeds 3 SD of the mean breath time for an infant or a child at any particular age. This definition requires data from a population of infants at a particular age, lacks physiologic value, and does not differentiate between relatively shorter or longer respiratory pauses. Alternatively, the definition of apnea may be based on the fact that respiratory pauses are associated with cardiovascular or neurophysiologic changes. Such definition relies on the functional assessment of pauses and is therefore more relevant

clinically. Because infants have higher O_2 consumption (per unit weight) than the adult and relatively smaller lung volume and O_2 stores, it is possible that short (e.g., seconds) respiratory pauses that may not be clinically important in the adult may present serious consequences in the very young or premature infant. Independent of age group, respiratory pauses are more prevalent during sleep than during the waking state. The frequency and duration of respiratory pauses depend on the sleep state in human infants. Respiratory pauses are more frequent and shorter in REM than in quiet sleep and are more frequent in younger than in older infants.

Although there is controversy regarding the pathogenesis of respiratory pauses, there is a consensus about certain observations. Normal full-term infants, children, and adult humans exhibit respiratory pauses during sleep. Paradoxically, some believe that the presence of respiratory pauses and breathing irregularity is a “healthy” sign and that the complete absence of such pauses may be indicative of abnormalities. However, prolonged apnea can be life threatening. The pathogenesis of these apneas may relate to the clinical condition of the patient at the time of the apnea, associated cardiovascular (systemic or pulmonary) changes, the chronicity of the clinical condition, the perinatal history, and whether the cause is central or peripheral. Prolonged apneic spells require therapy and, optimally, treatment should be targeted to the underlying pathophysiology.

UPPER AIRWAY OBSTRUCTION (see Chapter 20.5 and Chapter 369).

Upper airway obstruction (UAO) during sleep is recognized with increasing frequency in children. Many of these children have anatomic abnormalities. A common cause of UAO in children is tonsillar and adenoidal hypertrophy caused by repeated upper respiratory tract infections. Other associated abnormalities include craniofacial malformations, micrognathia, and muscular hypotonia. The usual site of obstruction in UAO in both infants and adults is the oropharynx, between the posterior pharyngeal wall, the soft palate, and the genioglossus. During sleep (especially REM sleep), upper airway muscles, including those of the oropharynx, lose tone and trigger an episode of UAO. The treatment should be targeted primarily at the underlying cause of obstruction.

Chapter 357 - Respiratory Pathophysiology

J. Julio Pérez Fontán
Gabriel G. Haddad

In humans, the respiratory system consists of a pumping mechanism (the respiratory muscles, the chest wall, and the conducting airways), a membrane gas exchanger (the interface between the air spaces and the pulmonary circulation), and a central neural control connected to a network of chemical and mechanical sensors distributed throughout the circulation and the components of the respiratory system itself. Basic to this arrangement is the close integration of respiratory and circulatory functions, which ensures not only the efficiency of gas exchange but also the ability to adapt oxygen uptake and carbon dioxide elimination to the variable demands of life. Alterations in the components of the respiratory system or its interaction with the circulatory system give rise to a variety of clinical manifestations. The most severe of these manifestations is the development of abnormal partial pressures of carbon dioxide (P_{CO_2}) and oxygen (P_{O_2}) in the arterial blood, a situation known as respiratory failure.

Respiratory Distress and Respiratory Failure.

The function of the respiratory pump is regulated by a highly responsive neuronal network that integrates chemical signals from chemoreceptors located in the ventral reticular nuclei of the medulla (central chemoreceptors sensitive to pH and P_{CO_2}) and carotid bodies (peripheral chemoreceptors, sensitive to P_{O_2}) and from mechanoreceptors located in the lungs to influence the neural output to the respiratory muscles. Increases in arterial P_{CO_2} (hypercapnia) and decreases in arterial P_{O_2} (hypoxemia) trigger an immediate increase in this output, which is distributed primarily to various spinal nuclei innervating either the diaphragm or muscles such as the scalenes and abdominal muscles, the latter being muscles that do not participate in normal breathing at rest (accessory muscles). The result is an increase in minute ventilation (the product of tidal volume and breathing frequency), which may return, under some circumstances, the P_{CO_2} and P_{O_2} to the physiologic range. Consequently, even before respiratory failure occurs, respiratory disease is usually detected either as an apparent or a subjective increase in the effort that the individual makes during breathing or as a limitation in the respiratory system's ability to accommodate increased demands for gas exchange, such as those created by exercise or fever. The development of arterial hypoxemia and especially hypercapnia without increase in the respiratory effort should always raise strong suspicion of an anomaly in the neural control of breathing, which can be the result of a central nervous system (CNS) injury (e.g., trauma, intracranial hemorrhage), drug-induced inhibition of the inspiratory neuronal network (e.g., opioid intoxication), or dysfunction/injury of the spinal motor neurons or nerve fibers that innervate the respiratory muscles (e.g., polyneuritis).

The timing and force of the respiratory effort elicited by a chemoreceptor stimulus and the specific muscles that participate in this effort are influenced by sensory inputs from mechanoreceptors distributed throughout the conducting airways, lung parenchyma, and chest wall. These inputs act through a system of neuronal relays to modulate the activity of inspiratory and expiratory premotor neurons in the medulla, modifying the duration of inspiration and expiration (and thus the breathing frequency), the tidal volume, and the specific sequence in which the respiratory muscles become recruited. This results in the adoption of a breathing pattern that is best suited for the specific mechanical conditions of the respiratory system. By observing the characteristics of this pattern, the experienced clinician can often infer a substantial amount of information about the nature of a respiratory impairment.

Work and Energy Cost of Breathing.

Most forms of respiratory disease involve anomalies in the mechanical function of the lungs or chest wall. From a physiologic point of view, the effect of these anomalies is an increase in the work that the respiratory muscles must do to keep up with the body's demands for gas exchange. The increased work is frequently accommodated through an increase in the neural drive to the respiratory muscles, which may be perceived by the patient as shortness of breath *(dyspnea)* or by an observer as *respiratory distress*. On occasion, however, the workload demands cannot be met by the contractile machinery of the respiratory muscles and *respiratory failure* ensues (see Chapter 357.1).

1363

In the case of breathing movements, work is defined as the product of lung volume change by the pressure that the respiratory muscles must generate to produce that volume change. This product is graphically represented by the area enclosed between the volume-pressure relationships of the lungs and chest wall and the volume axis (Fig. 357–1). Volume-pressure relationships are determined by properties that define the ease with which the lung tissue is stretched or the amount of resistance that the airways oppose to the passage of air. Thus, the work of breathing describes in one single value the overall mechanical behavior of the respiratory system, providing in the process a valuable account of the energy cost of the breathing activity.

Figure 357-1 Idealized elastic volume-pressure relationships of the lungs, chest wall, and respiratory system in the adult and the infant. Volume is expressed as a proportion of vital capacity (VC). At any volume, the pressure that the respiratory muscles generate to oppose the elastic recoil of the respiratory system is equivalent to the sum of the recoil pressures of lungs and chest wall. The intersection of each relationship with the volume axis corresponds to the relaxation volume of each component (the volume at which the elastic recoil is zero). The volume-elastic pressure relationships

of the lungs are similar in the adult and infant. The volume-elastic pressure relationship of the chest wall is steeper in the infant, causing the relaxation volume of the respiratory system to be lower than in the adult. The *shaded area* represents the elastic work done by the respiratory muscles for a characteristic tidal volume. Note that this work is greater in the infant because the recoil of the chest wall does not contribute to inflate the lungs as it does in the adult. (From Pérez Fontán JJ: Mechanics of breathing. In Gluckman PD, Heymann MA [editors]: *Perinatal and Pediatric Pathophysiology: A Clinical Perspective.* London, Edward Arnold, 1993.)

Restrictive and Obstructive Respiratory Dysfunction.

The respiratory muscles extract energy from the metabolic substrates that are brought to them by the blood. Energy is then transformed into physical work or is otherwise dissipated as heat. Depending on how energy is handled after its transformation into work, it is possible to divide the work of breathing into two components.

First, an important portion of the work of breathing produces reversible rearrangements of the alveolar gas-liquid interface and tissue molecular structures as the lungs and chest wall are stretched during inflation. As a result of their reversible nature, the energy stored in such rearrangements remains available to be used during deflation. These types of processes are responsible for the *elastic* properties of lung tissue. They are exemplified by the behavior of a rubber band, which stores energy when stretched and returns it when allowed to recover its original shape.

Another large portion of the work of breathing produces nonreversible molecular rearrangements or interactions. The energy so spent is permanently lost, usually by being converted into heat, which is then dissipated into the atmosphere or carried away by the circulating blood. All the mechanical processes that result in energy dissipation take place only in the presence of movement. As a result, the magnitude of the work done in connection with these processes bears a relationship to the rate at which gas flows in and out of the lungs. The decrease in alveolar pressure produced by the action of the inspiratory muscles is the reason why gas flows into the lungs during inspiration. The rate of flow is directly proportional to the pressure gradient and inversely proportional to the resistance of the conducting airways.

Establishing a diagnosis and formulating a therapy for children with respiratory disease is greatly aided by the clinician distinguishing between conditions that alter primarily the *elastic (restrictive respiratory disease)* and *resistive (obstructive respiratory disease)* properties of the respiratory system. This distinction is facilitated by an understanding of how these properties influence the physiologic behaviors of the lungs and chest wall.

Elastic Properties of the Respiratory System: Restrictive Respiratory Disease.

There are two primary structural reasons why the lungs and chest wall exhibit elastic behavior. First, the surface tension generated by the liquid film that lines the alveoli opposes lung inflation, particularly at low lung volumes when the air spaces are smaller and, in fulfillment of Laplace's law, the same surface tension causes the inward-acting pressure to increase. By coating the surface of the alveolar film with a monolayer of hydrophobic molecules, alveolar surfactant diminishes this pressure. Surfactant is less spread out when the surface area of the alveolar film contracts, and therefore it is more effective in reducing surface tension at low than at high lung volumes. Even in the presence of normal amounts of surfactant in the air spaces, surface tension is responsible for approximately 65% of the elastic recoil of the lungs. When surfactant is absent or dysfunctional *(respiratory distress syndrome of the newborn)* (see Chapter 90.3), elastic recoil becomes markedly increased and alveolar collapse ensues.

The fibrous scaffolding of the lungs and chest wall also imparts substantial elasticity to each of these components of the respiratory system. Particularly in the lungs, collagen and elastin fibers form a supportive web embedded in the alveolar walls and lung septa. This web is organized in a fashion that confers the tissues with a much greater ability to stretch and recoil than would be expected from the behavior of isolated fibers. In addition to allowing these tissues to expand and retract during breathing without generating undue tension, both the alveolar surfactant and the fibrous scaffolding play a critical role in preserving alveolar and airway stability. By reducing surface tension homogeneously throughout the lung, alveolar surfactant prevents small alveoli from emptying into larger ones, as it happens with soap

bubbles over time. By anchoring different intrapulmonary structures to each other, septal fibers ensure that the recoil forces generated within the lungs by the action of the respiratory muscles are evenly transmitted to alveolar walls, airways, and vessels. The ensuing *mechanical interdependence* between alveoli, airways, and pulmonary vessels keeps lung inflation homogeneous within the constraints imposed by the shape of the chest wall.

Both surface tension and elastic forces generated by lung fibers depend on the dimensions of the air spaces. Thus, it is not surprising that the overall elastic recoil of the lungs is highly dependent on lung volume just like, in the example of the rubber band, tension depends on the extent to which the rubber band is stretched. The relationship between volume and elastic pressure can be obtained easily for the lungs and the chest wall together or independently by measuring the corresponding pressure changes while the lungs are passively inflated and deflated in a stepwise manner (see Fig. 357–1). All three relationships are sigmoid. Volume therefore increases much less for a given pressure change at low and high volumes than at the intermediate volumes at which normal breathing takes place. In this range, the relationship is steeper and relatively linear and can therefore be described accurately by a fixed ratio of volume to pressure changes, which defines the concept of *compliance*.

Two premises define these interactions. First, at any volume the elastic recoil of the respiratory system is equal to the sums of the individual elastic recoils of the lungs and chest wall. Second, the volume changes experienced by the lungs, the chest wall, and the respiratory system are identical. Thus, pleural pressure (which, when the respiratory muscles are relaxed, represents the elastic recoil of the chest wall) may be high in a patient with asthma who has no intrinsic chest wall anomalies but whose lung volume is markedly increased by gas trapping. Because the heart and vessels inside the thorax are exposed to pleural pressure, cardiac output and arterial blood pressure often undergo an exaggerated decrease during inspiration as lung

volume increases even further *(pulsus paradoxus)*.

A similar analysis also demonstrates some other principles that regulate lung volume. Each relationship crosses the volume axis at a different point, regardless of age (see Fig. 357–1). This point defines the *relaxation volume*, which is the volume at which no elastic recoil is generated. Under normal conditions, the relaxation volume of the lungs is considerably smaller than that of the chest wall, a discrepancy that has several important consequences. First, it forces the respiratory system as a whole to adopt a relaxation volume intermediate between that of the lungs and that of the chest wall. After the newborn period, this volume coincides with the *functional residual capacity*, the gas volume of the lungs at the end of a tidal expiration (Fig. 357–2). In addition, the opposing recoils of the lungs and the chest wall at the relaxation volume of the respiratory system create a negative pleural pressure; this pressure promotes the return of venous blood into the heart and keeps the lung and chest wall attached to each other. If the pleural space were open to the atmosphere and the lungs and the chest wall were allowed to change volume freely, the lungs would collapse and the chest wall would expand. This is precisely what happens when a *pneumothorax* develops (see Chapter 403). Finally, for at least a portion of the volume range, the outward-acting recoil of the chest wall helps the expansion of the lungs, thereby reducing energy expenditure during inspiration.

Restrictive lung disease occurs when surface tension is abnormally high (e.g., respiratory distress syndrome of the newborn) (see Chapter 90.3), when the geometry or composition of the solid constituents of the lung is altered (e.g., interstitial edema, pneumonitis, fibrosis), or when the alveolar spaces are filled with liquid or inflammatory cells that limit their ability to admit gas (e.g., alveolar edema, pneumonia). *Restrictive chest wall disease*, in contrast, is usually caused by structural anomalies of the chest wall itself (e.g., scoliosis, rib cage dystrophy), neuromuscular disease, or, most commonly, abdominal distention. Whether originating in the lungs or the chest wall, restrictive respiratory disease has some unique clinical characteristics (Table 357–1). First, only the work performed during inspiration increases, and thus the extra load is carried almost exclusively by the inspiratory muscles, the diaphragm in particular. Second, the patient typically tries to minimize energy demands by adopting a pattern of rapid and shallow breathing, which, when present, almost always indicates a restrictive derangement. Last, the increased elastic recoil of the lungs or the chest wall lowers the relaxation volume of the respiratory system as a whole. Consequently, the functional residual capacity and, to a more variable extent, the forced vital capacity are reduced in all forms of restrictive disease (see Fig. 357–2). Because the recoil forces

Figure 357-2 Effects of restrictive and intrathoracic obstruction on the divisions of total lung capacity. Functional division of total lung capacity. Restrictive disease is usually characterized by a pattern of shallow, rapid breaths. All lung capacities (total lung capacity, functional residual capacity, and vital capacity) are reduced owing either to the increased recoil of the lungs or to the presence of a space-occupying lesion that limits lung inflation. Residual volume is often decreased (as shown in the illustration) but may also be increased if an abnormal configuration of the chest prevents the lungs from deflating completely. Intrathoracic obstruction impairs the ability of the lungs to deflate and thus causes gas trapping, increasing functional residual capacity and residual volume at the expense of vital capacity. The volume exhaled in the first second of a forced expiration ($FEV_{1.0}$) is reduced in both restrictive and obstructive disease. The ratio of $FEV_{1.0}$ to vital capacity, however, is maintained in the former and decreased in the latter.

TABLE 357-1 -- **Characteristic Clinical Findings of Restrictive and Obstructive Lung Disease in Infants and Children**

		Obstructive Disease	
Finding	**Restrictive Disease**	***Extrathoracic***	***Intrathoracic***
Breathing rate	Increased	Decreased	Normal or increased
Duration of inspiration	Reduced	Prolonged	Unchanged
Duration of expiration	Reduced	Unchanged	Prolonged
Accessory respiratory muscles	Inspiratory	Inspiratory	Inspiratory and expiratory (abdominal)
Rib cage distortion (retractions)	Present	Present	Often present
Amplitude of breathing movements	Shallow	Normal or reduced	Normal or reduced
Auscultatory findings	Crackles, grunting	Inspiratory stridor	Expiratory wheezing
Radiographic appearance of lungs	Decreased lung volume, alveolar densities	Normal	Increased lung volume

transmitted through the fibrous network of the lungs are minimal at low lung volumes, alveoli become unstable and alveolar collapse tends to complicate the situation by further decreasing ventilation-perfusion ratios and causing hypoxemia.

Resistive Properties of the Respiratory System: Obstructive Respiratory Disease.

The resistive behavior of the respiratory system results from molecular rearrangements and interactions initiated by motion. The most important of these interactions results from the collision of air molecules against the airway walls, a phenomenon that gives rise to friction. When friction is the only factor, Poiseuille's law predicts that the pressure losses are directly proportional to the viscosity of the gas, the length of the pipe, and the rate of airflow, and inversely proportional to the fourth power of the airway's radius. Thus, it is easy to understand how airway diseases such as *croup* or *viral bronchiolitis* increase the work of breathing more in newborns and small infants, who have smaller radius airways, than in older children. However, friction is not the only source of resistive work. Molecular interactions and velocity changes within the breathing gas itself, particularly when the flow becomes turbulent in pathologically narrow portions of the airways, can result in considerable energy dissipation. Unlike wall friction, the pressure needed to overcome turbulence

depends on the density and not on the viscosity of the gas. This is the reason why children with *croup* have less respiratory difficulty and stridor when the air they breathe is replaced with a mixture of oxygen and helium, which has a lower density than air or oxygen (even if its viscosity is slightly higher). Finally, nonreversible molecular rearrangements within the tissue or the gas-liquid interface play an important role in the resistive properties of the lungs and the respiratory system as a whole.

The resistive behavior of the respiratory system can also be analyzed graphically (Fig. 357–3). The volume-pressure relationships of the lungs, chest wall, and respiratory system as a whole form characteristic loops; they show *hysteresis*, which means that the relationships have different courses during inspiration and expiration. The presence of hysteresis always denotes that there is an energy loss from the system. Moreover, the greater the hysteresis, the larger is this energy loss. Accordingly, the width of the loop formed by the pressure-volume relationships of the respiratory system or its components (which has the units of pressure) can be used as a quantitative estimate of resistive behavior. When divided by the rate of gas flow, it yields the *resistance* of each component, a measurement that summarizes various properties that cause resistive energy dissipation. The graphic analysis of the volume-pressure relationships of the respiratory system also reveals that, even though resistive work is done during inspiration and expiration, usually the inspiratory portion of the work is the only one that represents an energy burden. Under normal circumstances, expiration does not require the contraction of any muscles and all expiratory resistive work is performed by the elastic recoil accumulated during inspiration in the lungs and chest wall. However, when expiratory resistance is elevated by disease (e.g., asthma, bronchiolitis) or when the individual needs to accelerate the emptying of the lungs to increase ventilation (e.g., during exercise or when the intrathoracic airways are obstructed), abdominal and other accessory muscles of expiration become engaged. This engagement in a resting child is usually a good indication of the presence of obstructive respiratory disease.

Proper diagnosis and evaluation of airway obstruction require additional understanding of the relationships between airway caliber and lung volume. Airway caliber is determined by the coupling of airway wall elasticity and airway transmural pressure. The former depends on the state of health and maturity of the airway tissue (immature airways tend to collapse more easily) and is influenced by the tone of the muscles contained in the airway wall. This tone is, in turn, regulated by neural efferents, which are activated by the CNS to stiffen the airway walls, particularly under conditions in which breathing activity must increase (during exercise, hypoxia, or hypercarbia).

Figure 357-3 Graphic analysis of the resistive behavior of the respiratory system during a tidal breath. In the presence of airway flow, energy dissipation causes the relationship between lung volume (expressed as a proportion of vital capacity) and the pressure that the respiratory muscles must generate to form a loop (hysteresis). The area enclosed by this loop represents the work done to overcome resistive pressures such as those caused by the friction of the air against the airway walls. Only the inspiratory portion of this work (W_{resI}), however, is performed by the respiratory muscles. The expiratory portion (W_{resE}) is done by the energy accumulated in elastic elements of the respiratory system during inspiration. (From Pérez Fontán JJ: Mechanics of breathing. In Gluckman PD, Heymann MA [editors]: *Perinatal and Pediatric Pathophysiology: A Clinical Perspective.* London, Edward Arnold, 1993.)

Airway transmural pressure is the difference between the pressures acting on the inside and outside surfaces of the airway wall. It varies during the respiratory cycle in a fashion that depends on whether the airways are intrathoracic or extrathoracic. Extrathoracic airways (nose, pharynx, larynx, the extrathoracic portion of the trachea) are exposed to atmospheric pressure on the outside. Because the pressure acting on the inside surface is subatmospheric during inspiration and supra-atmospheric during expiration, the transmural pressure in this portion of the airway is always negative (narrowing or even collapsing the airway) during inspiration and always positive (dilating the airway) during expiration. The outside surface of the intrathoracic airways is exposed either to pleural pressure (trachea and main bronchi) or to the stresses generated by lung inflation within the lung tissue (intrapulmonary bronchi, bronchioles, and alveolar ducts). These stresses are transmitted to the airway walls by their tissue attachments to the alveolar septa and, when averaged, they add up to a value close to the pleural pressure. During inspiration, the pressure inside the airways is greater than the pressure inside the alveoli. Alveolar pressure, in turn, is always greater than pleural pressure (otherwise, the lungs would have a negative elastic recoil). Consequently, the transmural pressure of the intrathoracic airways always becomes more positive (dilating the airways) as the lungs inflate. During expiration, in contrast, the pressure at all points inside the airways must be lower than alveolar pressure. Whether the pressure inside a certain point in the airways is higher or lower than pleural pressure, however, depends on how much pressure has been lost upstream from the point in question. If the loss is large, the pressure inside the intrathoracic airways can become lower than pleural pressure. The transmural pressure then becomes negative and the airway tends to collapse, a problem that is compounded further if the airway wall is abnormally soft (in the premature infant or in children who suffer from *tracheobronchomalacia*). The more the subject tries to overcome the resultant increase in expiratory resistance by making use of the expiratory muscles, the more the pleural pressure increases and the more the airway collapses, leading to a situation in which outward airflow cannot increase any more regardless of the effort. The expiratory flow at which such *flow limitation* occurs is reproducible for a given lung volume. Determinations of maximal expiratory flow during respiratory function testing take advantage of this reproducibility to evaluate and follow the function of the intrathoracic airways over time or in response to specific therapies.

Airway obstruction causes an exaggeration of the normal changes in airway caliber. When the extrathoracic airway is obstructed (croup, foreign body), the pressure inside the airways distal to the narrowing becomes more negative during inspiration through the actions of the diaphragm and other inspiratory muscles to overcome the increased resistance at the point of obstruction. Therefore, the extrathoracic airway collapses downstream from the level of the obstruction, usually causing an audible vibration or inspiratory *stridor* as the gas rushes through the obstruction. When the intrathoracic airway is obstructed (asthma, foreign body), the pleural pressure must become more positive during expiration. Because the inside pressure beyond the obstruction decreases, the intrathoracic airways downstream from the obstruction tend to collapse, producing an exacerbation of the obstruction, audible expiratory *wheezes*, and flow limitation at low expiratory flows.

Distinction between Restrictive and Obstructive Respiratory Dysfunction: Pulmonary Function Testing.

A careful physical examination frequently yields sufficient information to establish whether an infant or child is suffering from a predominantly restrictive or obstructive ailment (see Table 357–1). However, complicated diagnostic problems and the follow-up of those patients for whom a diagnosis has already been made are aided greatly by the performance of pulmonary function tests. These tests combine gas flow and lung volume measurements to characterize in detail each patient's physiologic derangement. Gas flows rates are most informative if measured during a forced expiratory maneuver generated either voluntarily, if the patient is old enough to cooperate, or by wrapping the chest in an inflatable jacket, when the patient is too young or uncooperative. In addition to being relatively simple to determine, gas flow rates obtained under conditions of flow limitation in the airways are highly reproducible and thus can be compared over time.

Expiratory flow measurements are easier to interpret if flow is plotted against lung volume, forming characteristic flow-volume loops (Fig. 357–4). As a basic principle in the interpretation of these loops, restrictive disease causes proportional decreases in flow rate and lung volume; obstructive disease decreases flow rate but not lung volume.

Lung volume measurements can be obtained either with a body plethysmograph or by combining spirometry and gas dilution or washout techniques (see Fig. 357–2). Typically, both intrathoracic airway obstruction and restrictive respiratory disease reduce vital capacity, but as indicated in Figure 357–2 , testing usually distinguishes the two disease categories.

Combinations of restrictive and obstructive disease are not uncommon and, when present, are difficult to diagnose by pulmonary function testing alone. The presence of restrictive disease should be suspected whenever gas flow rates are decreased out of proportion with the FEV_1 /vital capacity ratio or when the total lung capacity is reduced.

Response to Respiratory Disease: Efficiency of the Developing Respiratory System.

When the respiratory workload increases in the course of an illness, the respiratory system initiates two responses. The most immediate is to increase the output of the respiratory muscles at the cost of increased energy expenditure. This response is limited not only by substrate availability but also by the ability of the muscles to generate a maximal contraction force. The second response is usually an attempt to improve the efficiency of respiration by changing the respiratory pattern.

The respiratory system is inherently inefficient with values as low as 8% (indicating that only 8% of the energy consumed by the muscles is transformed into actual volume-pressure work) reported in resting adults. Even lower values have been suggested in term newborn and premature infants. Because the baseline values are so low, disease-induced changes in efficiency usually have a large effect on the energy required for breathing. Factors that determine respiratory system efficiency include the breathing pattern; the configuration, length, and functional state of the diaphragm; and the degree of chest wall distortion that occurs with each breath.

Each *breathing pattern* is a unique combination of breathing frequency and tidal volume. Different breathing patterns can yield the same minute ventilation, but there is only one specific respiratory pattern that results in minimal energy expenditure at any time. This optimal pattern varies predictably depending on the mechanical characteristics of the respiratory system. Breathing frequency, for instance, increases when elastic recoil becomes greater in the course of a restrictive derangement. In contrast, the frequency decreases when the resistive properties of the respiratory system become exaggerated by airway obstruction. It is therefore possible to categorize respiratory disease as primarily restrictive or obstructive, depending on whether the patient breathes rapidly and shallowly or slowly and more deeply. It is important to remember, however, that breathing pattern is regulated by influences other than energetic considerations. It is common for children with respiratory disease to breathe transiently at frequencies that depart substantially from optimum. Crying and agitation can in this manner reduce the efficiency of the respiratory system and, in extreme circumstances, precipitate respiratory failure.

Figure 357-4 Flow volume loops obtained by plotting the gas flow generated during a forced vital capacity maneuver in which, after a forced exhalation, the subject inhales to vital capacity and exhales to residual volume. The direction of the loops is clockwise. Inspiration is downward; expiration is upward. $_{max}$ represents peak expiratory flow. $_{maxFRC}$ is the maximal flow recorded at functional residual capacity. Restrictive disease reduces lung volumes and both inspiratory and expiratory flow rates without changing the shape of the loop. Extrathoracic obstruction is exacerbated during inspiration and thus flattens the inspiratory limb of the loop without altering the expiratory limb. Intrathoracic obstruction increases functional residual capacity and reduces all expiratory flows. The flow reduction becomes more severe as lung volume decreases, creating a characteristic concavity or “scoop” in the expiratory limb of the loop.

Like other skeletal muscles, the *diaphragm* can develop its maximal force only if it starts its contraction from an optimal length. This length is attained when the lungs approximate their functional residual capacity (see Fig. 357–2). At this volume, the diaphragm adopts the shape of a dome-capped cylinder. In addition to increasing the volume displaced for a given fiber shortening, this shape allows for a certain area of the diaphragm's thoracic surface to be in direct apposition to the rib cage. This allows the abdominal contents to push the lower ribs forward and laterally during inspiration, increasing the volume of the lungs. The less steep dome shape of the diaphragm in the infant, particularly in the newborn, may not take advantage of these features. The lower portion of the rib cage has large anteroposterior and lateral diameters. As a result, the diaphragmatic insertions are spread out, limiting the range of lengths of the diaphragmatic fibers.

Chest wall distortion can occur at all ages and results primarily from the fact that the chest wall does not have a homogeneous structure or expand uniformly during lung inflation. Areas with no bony support, like the intercostal spaces, tend to move inward under the effects of negative pleural pressure during inspiration. This movement is exaggerated whenever the pleural pressure becomes more negative than normal in the presence of lung disease, creating visible *retractions*. The limited ossification of the ribs and sternum makes the chest walls of newborns and infants

very compliant (see Fig. 357–1), a feature that facilitates the birth process but also creates some mechanical liabilities. First, it decreases the relaxation volume of the respiratory system, forcing the newborn to acquire strategies to maintain the functional residual capacity within acceptable limits. These strategies, which are generally based on delaying expiration, are easily overwhelmed when lung compliance is reduced by disease, when neurologic control is impaired by CNS injury or sedation, or when the tone of the chest wall muscles is decreased during rapid eye movement sleep. Because the functional residual capacity represents the largest oxygen store in the body, its reduction in infants can easily lead to hypoxemia because of the high oxygen consumption rates characteristic at an early age. In addition, a high chest wall compliance promotes increased regional distortion of the rib cage. The clinician must be aware that rib cage retractions are not only a sign of disease but also represent a form of work and may have a substantial energy cost. This is particularly true in premature infants, whose diaphragms may do more work to distort the rib cage than to inflate the lungs, even in the absence of lung disease.

The Lung as a Gas Exchanger

SPECIAL CHARACTERISTICS OF THE PULMONARY CIRCULATION.

Gas exchange in the lungs takes place in millions of small units, each consisting of a pulmonary capillary and the neighboring portion of the air space. Before arriving there, the venous blood returning to the heart is propelled by the right ventricle into a branching network of pulmonary vessels.

After the adaptations that take place during the newborn period (see Chapter 90.1), the pulmonary circulation offers a much lower resistance to the passage of blood than does the systemic circulation. As a result, the pulmonary blood flow can be accommodated with relatively low blood pressures in the pulmonary artery, allowing the right ventricle to lose part of its muscle mass to become a chamber more adapted to handle volume than pressure loads. Reversal of this situation occurs in a variety of clinical situations, which, as a common denominator, cause *pulmonary arterial hypertension* (defined as an abnormal increase in pulmonary arterial pressure). Physiologic stimuli such as chronic hypoxemia and increased shear stress or tension in the vascular walls can produce smooth muscle hypertrophy and deposition of elastin and type I collagen, leading eventually to the obliteration of pulmonary vessels in experimental animals. Similar stimuli and possibly a failure to curtail the cell and fibroproliferative response that they induce in the vascular wall are the origin of many cases of pulmonary hypertension complicating parenchymal lung disease, left ventricular inflow or outflow obstructions, or left-to-right shunts in childhood.

Pulmonary arterioles (the resistance vessels in the pulmonary circulation) are considerably more reactive to changes in P_{o_2} and P_{co_2} in their environment than are systemic arterioles. Even small fluctuations in these partial pressures can cause marked changes in pulmonary vascular tone. Alveolar hypoxemia is a particularly powerful vasoconstrictive stimulus, which provides the lungs with a local regulatory system to minimize arterial hypoxemia by directing nonoxygenated blood away from areas where ventilation-perfusion ratios are low. Hypercarbia produces pulmonary vasoconstriction; hypocarbia causes pulmonary vasodilation. The effects of oxygen and carbon dioxide on the pulmonary circulation are opposite to those on the cerebral circulation.

Pulmonary capillaries also have a distinctive structural characteristics that reflect their gas exchanging function. Their wall is formed by extraordinarily thin projections from endothelial cells. Because the alveolar epithelium is also very thin, blood and alveolar gas are only separated by less than 1?µm, a feature that explains the ease with which oxygen and carbon dioxide diffuse from one space to the other. In addition, rather than displaying the treelike distribution found in the vascular beds of other organs, pulmonary capillaries form a dense lattice of intercommunicating short segments. Blood circulates through these circuitous pathways, forming a continuous sheet interrupted only by small islands of connective intercapillary tissue. This arrangement enhances the contact surface between the blood and the alveolar gas, minimizes vascular obstruction when the alveoli become distended, and can accommodate easily the increased blood flow needed during exercise or disease. Alveolar capillary growth lags behind alveolar development, and newborn animals have a limited ability to expand their pulmonary capillary bed much beyond the resting state. This may promote pulmonary hypertension when pulmonary blood flow is increased (e.g., left-to-right shunts) or when disease or developmental abnormalities reduce the cross section of the capillary bed (e.g., unilateral lung hypoplasia or after lobectomy or pneumonectomy).

Extra-alveolar vessels (arteries and veins) are for the most part intrapulmonary structures (arteries follow the airways into the acinus whereas veins are interacinary) and, as such, they are subjected to the forces generated inside the lungs during breathing. These forces are transmitted to the vessel wall by the vessel's attachments to the fibrous scaffolding of the lung. Alveolar vessels, in contrast, are contained entirely in the alveolar walls and therefore become compressed as the lungs inflate and the alveolar pressure rises relative to pleural pressure (which is the pressure to which the heart and major vessels are exposed). Because the effect of inflation over the extra-alveolar vessels predominates at low lung volumes and the effect over the alveolar vessels predominates at high lung volumes, the total resistance of the pulmonary circulation follows a biphasic U-shaped relationship with respect to lung volume, decreasing at low lung volumes and increasing at higher lung volumes. The inflection point of the relationship, where resistance is minimal, coincides with the functional residual capacity, which therefore represents the point at which pulmonary blood flow is maximal for any given pulmonary arterial pressure. Decreases in lung volume (e.g., alveolar collapse) and lung overinflation (e.g., asthma or excessive distention during mechanical ventilation) increase pulmonary vascular resistance and the afterload to the right ventricle.

Finally, the pulmonary circulation is the site of an active exchange of water and solutes between the vascular space and the interstitium of the lung (the continuous space that exists between alveolar epithelium and endothelium and around airways and pulmonary vessels). The exchange occurs across the endothelial cells or the interendothelial cell junctions and is regulated by a balance of hydrostatic and protein osmotic (oncotic) forces. Increases in fluid filtration, leading to pulmonary edema, occur either when the microvascular pressures increase relative to the protein osmotic pressures (e.g., left ventricular failure, pulmonary venous obstruction) or when the water and solute permeability of the endothelium is increased (in virtually

any form of lung injury). Confined initially to the pulmonary interstitium, fluid is removed by an effective system of lymphatic vessels. When the capacity of these vessels is exceeded, however, fluid can penetrate the alveolar spaces, interfering even further with both the mechanical function of the lungs and gas exchange.

FACTORS DETERMINING THE EFFICIENCY OF GAS EXCHANGE IN THE LUNGS.

The arterial blood is a weighted mixture of the blood that passes through all the alveolar-capillary units of the lungs. Even under normal circumstances, there are substantial differences in the composition of the capillary blood emerging from different units. These differences are greatly exaggerated by disease, which, no matter how diffuse and apparently homogeneous, tends to affect the microscopic elementary units of the lung in an uneven manner. Thus, it is not surprising that ventilation-perfusion inequalities are the main mechanism of hypoxemia in most children with lung disease. To understand in more detail how this happens, however, it is important to know the individual processes involved in the transfer of oxygen and carbon dioxide from the atmosphere to the blood.

Ventilation is the process by which the alveolar gas is renewed during breathing. It involves a reciprocating movement of fresh or inspired gas (typically air) into the distal portions of the lung and expired gas into the atmosphere. Only a portion of the gas that enters or leaves the lungs in a unit of time (minute ventilation), however, participates in gas exchange. This portion, known as the alveolar ventilation, is defined as a function of the ratio of carbon dioxide production (or elimination) and alveolar P_{co_2} (e.g., alveolar P_{co_2} or, by extension, arterial P_{co_2} is proportional to carbon dioxide production and inversely proportional to minute alveolar ventilation). The difference between minute ventilation and minute alveolar ventilation is known as the *dead space ventilation* and represents the part of the minute ventilation that does not take part in gas exchange. It includes both gas that remains in the conducting airways (anatomic dead space) and gas that reaches alveolar spaces but does not equilibrate its composition with capillary blood (alveolar dead space). Dead space ventilation is usually increased by respiratory disease because of the presence of a large number of gas exchange units with high ventilation-perfusion ratios.

Oxygen and carbon dioxide enter the pulmonary capillary blood by a process of diffusion driven by the partial pressures of these gases in the capillary blood and the alveolar gas. The blood that enters the pulmonary capillaries is venous blood and has a relatively fixed composition, dictated primarily by the transformations that have occurred in the once arterial blood as a result of tissue respiration. The composition of the alveolar gas, on the other hand, is dictated by the efficiency with which alveolar gas is renewed by ventilation and the efficiency with which oxygen and carbon dioxide are transported in and out of the alveoli by the blood. With other factors being constant, increases in gas flow (ventilation) with respect to blood flow (perfusion) augment alveolar and pulmonary capillary P_{o_2} and decrease alveolar and pulmonary capillary P_{co_2} . Conversely, a reduction in the ventilation-perfusion ratio decreases alveolar and pulmonary capillary P_{o_2} . Alveolar P_{o_2} and P_{co_2} (and arterial P_{o_2} and P_{co_2}) are bound, both at the level of each alveolus and for the lung as a whole, by a mathematical relationship *(the alveolar gas equation)* that takes into account the composition of the inspired gas and the relative flows of carbon dioxide and oxygen across the alveolar-capillary membrane (the quotient known as the *respiratory exchange ratio*, R):

where P_{ao_2} represents the alveolar P_{o_2} , P_{io_2} the partial pressure of inspired oxygen (calculated by multiplying the inspired oxygen concentration, F_{io_2} , by the difference between the atmospheric

pressure and the water vapor pressure at body temperature), and P_{aco_2} is the alveolar P_{co_2} (replaced in practice with the arterial P_{co_2}). The last term of this equation is small when the subject is breathing room air; under those circumstances:

Global decreases in ventilation or *hypoventilation* are relatively rare in a pure form and are usually caused by CNS dysfunction, impaired nerve conduction, or muscle weakness or fatigue. These conditions reduce the rate at which the alveolar gas is renewed, and therefore they increase alveolar P_{co_2} and decrease alveolar P_{o_2} , each by a magnitude predicted by the alveolar gas equation. Because hypoventilation interferes only with the composition of the alveolar gas, there is very little difference between the alveolar and the end-capillary P_{o_2} . Thus, the difference between the alveolar P_{o_2} (estimated by the alveolar gas equation) and the arterial P_{o_2} remains small, a characteristic that is unique to the hypoxemia caused by hypoventilation. Administration of supplemental oxygen increases the inspired P_{o_2} and corrects the hypoxemia readily.

From the alveoli, oxygen and carbon dioxide diffuse into the alveolar capillaries along their respective partial pressure gradients. In this process, an oxygen molecule crosses a portion of the alveolar space, the cytoplasms and basal membranes of the alveolar epithelium and endothelium, a certain distance within the plasma, and the membrane and cytoplasm of the erythrocyte, where it enters a chemical reaction with a hemoglobin molecule. This complex diffusion process occurs rapidly enough for all hemoglobin molecules to be saturated with oxygen by the time the erythrocyte has traveled one third of its trajectory within the alveolar wall. Because of the high diffusivity of both oxygen and carbon dioxide, diffusion defects are a very rare cause of hypoxemia and never a cause of hypercapnia in children at rest, even when there is substantial infiltration of the alveolar interstitium by fluid, inflammatory cells, or connective tissue. Occasionally, diffusion abnormalities become manifest as an increased alveolar-arterial P_{o_2} gradient under conditions that raise pulmonary blood flow (exercise, fever), leaving less time for equilibration of alveolar and capillary P_{o_2} .

Ventilation and diffusion define the potential for oxygen uptake and carbon dioxide elimination by individual alveolar-capillary units. Whether this potential can be reached is determined by blood flow. The terms *venous admixture* and *shunt* are used, often interchangeably, to describe a situation in which a portion of the blood that reaches the systemic circulation does not equilibrate its P_{o_2} with the alveolar gas. In a strict sense, these terms define an index calculated as the volume of venous blood that would have to be added to ideal capillary blood to reproduce the P_{o_2} of the arterial blood. Venous admixture can be caused by diffusion defects, ventilation-perfusion inequality, or true shunting of venous blood either through pulmonary blood vessels that supply nonventilated areas or through pathways that

bypass the alveolar spaces altogether. The hypoxemia caused by diffusion defects and ventilation-perfusion inequality is responsive to oxygen supplementation. The hypoxemia produced by true shunts, in contrast, cannot be corrected by oxygen administration because the increase in oxygen content of the blood that is exposed to the alveoli is usually insufficient to compensate for the shunt. A small amount of venous admixture is found in all normal individuals. It accounts for a small alveolar-arterial P_{O_2} difference, which varies with age and is usually less than 5–6?mm Hg in room air for the adolescent and is slightly larger for the infant. This difference is caused by normal shunt pathways between the pulmonary and systemic circulations and small inequalities in ventilation-perfusion matching. In the term newborn, and particularly in the premature infant, the alveolar-arterial P_{O_2} difference is even greater. Possible explanations are the larger diffusion distance between the immature saccules and saccular capillaries, heterogeneity of ventilation-perfusion ratios, and airway closure in the supine position.

Ventilation-perfusion inequality or *mismatch* has long been recognized as the main mechanism of the hypoxemia and hypercapnia in patients with lung disease. Two concepts are basic to the understanding of this mechanism. First, the oxygen and carbon dioxide contents of the blood that exits each individual alveolar-capillary unit depend on the relationship between the unit's ventilation and perfusion. In addition, the oxygen and carbon dioxide contents of the arterial blood are equivalent to the sum of the products of the oxygen and carbon dioxide contents by the blood flow through all the units that form the lungs. Areas with a low ventilation-perfusion ratio cause more of a decrease in arterial oxygenation than areas with a high ventilation-perfusion ratio increase it (Fig. 357–5). The reason is that in areas with a low ventilation-perfusion ratio, the hemoglobin-oxygen dissociation curve favors large decreases in the oxygen saturation and content of the capillary blood with small decrements in P_{O_2} . Conversely, in areas with a high ventilation-perfusion ratio, the oxygen saturation and content in the capillaries changes little, even with large increases in P_{O_2} . As a result, when the oxygen-desaturated blood from areas with a low ventilation-perfusion ratio mixes with oxygenated blood from other areas in the pulmonary veins, the overall oxygen saturation and P_{O_2} are lower than normal.

Figure 357-5 Diagram demonstrating the effects of decreased ventilation-perfusion ratios on arterial oxygenation in the lungs. Three alveolar-capillary units are illustrated. Unit A has normal ventilation and an alveolar P_{O_2} of 100?mm Hg (shown by the number in the middle of the air space). The blood that circulates through this unit raises its oxygen saturation from 70% (the saturation of mixed venous blood) to 99%. Unit B has a lower ventilation-perfusion ratio and a lower alveolar P_{O_2} of 60?mm Hg. The blood that circulates through this unit reaches a saturation of only 90%. Finally, unit C is not ventilated at all. Its alveolar P_{O_2} is equivalent to that of the venous blood, which travels through the unit unaltered. The oxygen saturation of the arterial blood reflects the weighted contributions of these three units. If it is assumed that each unit has the same blood flow, the arterial blood would have a saturation of only 86%. Ventilation-perfusion mismatch is the most common mechanism of arterial hypoxemia in lung disease. Supplemental oxygen increases the arteriol P_{O_2} by raising the alveolar P_{O_2} in lung units that, like B, have a ventilation-perfusion ratio greater than zero.

357.1 Respiratory Failure

J. Julio Pérez Fontán
Gabriel G. Haddad

Respiratory failure is defined in general terms as the situation in which the respiratory system cannot fulfill the gas exchange needs of the patient. Specifically, respiratory failure is defined by the presence of abnormalities in the arterial P_{O_2} and P_{CO_2} (also see Chapter 57). P_{O_2} and P_{CO_2} are tightly regulated by the central nervous system (CNS), and any alterations in their values can be taken as an indication that either the regulatory system (the breathing control) or its effector organs (the respiratory muscles and the lungs) have become impaired or overwhelmed. However, blood gas analysis requires time and should never delay the institution of lifesaving measures when the physical examination suggests that blood gas abnormalities are present or imminent. Moreover, the presence of an alteration in either the arterial P_{O_2} or P_{CO_2} is not sufficient for the diagnosis of respiratory failure, nor does its absence exclude this diagnosis. For instance, P_{O_2} can be decreased in patients with intracardiac right-to-left shunts and P_{CO_2} can be increased in patients with metabolic alkalosis, in both cases without intrinsic respiratory impairment. In contrast, arterial P_{O_2} may be normal even in the presence of a substantial derangement in gas exchange if the individual is breathing increased inspired oxygen concentrations.

Etiology.

Acute respiratory failure may occur de novo as a complication of diseases as varied as pneumonia, pulmonary edema caused by congestive heart failure, or airway obstruction (epiglottitis, asthma). It also frequently occurs as a complication of a chronic respiratory disease. Intercurrent illnesses such as those caused by the respiratory syncytial virus or influenza frequently overcome the ability of an infant or child with bronchopulmonary dysplasia or cystic fibrosis to compensate for a

pre-existing respiratory dysfunction. In some patients with compensated respiratory disease, even the relatively small increase in ventilatory demands created by an increase in temperature may be sufficient to precipitate worsening hypoxemia and hypercarbia.

Diagnosis.

Although the diagnosis of respiratory failure must ultimately rely on the demonstration of gas exchange abnormalities, these are rarely the first manifestations of respiratory impairment. In most instances, the infant or child is brought to medical attention because of other symptoms or physical signs, which sometimes are unrelated to the respiratory system. In evaluating these symptoms and signs, the clinician should always start by considering whether they correspond to one of three distinctive possible clinical profiles (Fig. 357–6). A rapid assignment to one of these profiles facilitates the identification of the cause of the respiratory failure and a more rational approach for the initial treatment.

The most common profile results from alterations in the mechanical function of the conducting airways, the lung parenchyma, or the chest wall. Airway dysfunction is usually manifested as obstructive disease, whereas lung parenchymal and chest wall dysfunctions are predominantly restrictive (see Chapter 357). Mechanical alterations do not impair the ability of the breathing control to increase neural output to the respiratory muscles in response to chemical or mechanical stimuli. Consequently, they are accompanied both by the patient's subjective perception of “air hunger” (dyspnea) and by an increase in respiratory muscle effort. The latter is responsible for the constellation of signs that define respiratory distress: tachypnea, intercostal and subcostal retractions caused by decreased pleural pressure during inspiration; recruitment of muscles that do not participate in normal breathing at rest (accessory muscles); and activation of the dilator muscles of the upper airway (most visible as nasal flaring). Depending on the specific mechanical alteration and the age of the patient, additional signs such as grunting (usually present when lung volume is rendered unstable by restrictive disease), stridor (indicative of extrathoracic airway obstruction), and expiratory prolongation and wheezing (indicative of intrathoracic airway obstruction) may be prominent.

The second profile results from alterations of the respiratory muscles (myopathy involving the respiratory muscles) or their innervation (polyneuropathy or phrenic nerve injuries). These are also associated with an increased neural output, but this cannot be conducted to the muscles or translated into effective respiratory contractions. Tachypnea with shallow respiratory efforts and profound dyspnea are characteristic, but intercostal or subcostal retractions may be absent.

The third profile results from alterations in the control of breathing itself (see Chapter 357.2), usually as a consequence of developmental anomalies (e.g., Ondine's course, apnea of prematurity), CNS injury (trauma, meningoencephalitis, or brainstem compression), or the effects of inhibitory drugs (opioids). These alterations are associated with decreased neural output to the respiratory muscles and therefore produce few or no signs of respiratory distress, even in the presence of considerable derangement in gas exchange.

MECHANICAL DYSFUNCTION AND COMPENSATION ABNORMALITIES.

Both restrictive and obstructive disease increase the work of breathing and therefore raise the energy demands of the respiratory muscles. If these demands are met, the mechanical abnormality remains compensated. If the demands exceed the capabilities of the respiratory muscles, respiratory failure develops. Under normal circumstances, energy availability greatly exceeds energy demands, and even substantial increases in the breathing workload can be compensated. However, when efficiency is reduced by rib cage distortion, abdominal distention, overinflation of the lungs, respiratory muscle fatigue, or malnutrition, insufficient energy is transformed into work and respiratory failure may result.

Recognizing the mechanisms that compensate for the increases in the work of breathing is just as important as blood gas analysis for the diagnosis and management of respiratory failure. These mechanisms involve an increased effort on the part of the respiratory muscles, which, similar to other skeletal muscles, can become fatigued when subjected to excessive demands over time. Respiratory muscle fatigue reduces the force generated by each contraction and impairs the ability of the respiratory system to sustain the compensatory response. Newborn infants have an increased propensity for respiratory muscle fatigue. This probably relates to decreased breathing efficiency (see Chapter 357) caused by mechanical factors such as the high compliance of the chest wall and the small surface of apposition of the diaphragm to the rib cage, rather than to maturational changes in the intrinsic properties of the respiratory muscles themselves. Other conditions frequently found in association with respiratory disease such as malnutrition, decreased perfusion, electrolyte disorders, and hypophosphatemia increase the vulnerability of the respiratory muscles to fatigue

---

Figure 357.1-6 Presentation profiles of respiratory failure in childhood. When a mechanical dysfunction is present (by far, the most common circumstance), arterial hypoxemia and hypercapnia (and hence pH) are sensed by peripheral (carotid bodies) and central (medullary) chemoreceptors. After being integrated with other sensory information from the lungs and chest wall, chemoreceptor activation triggers an increase in the neural output to the respiratory muscles (*vertical arrows*), which results in the physical signs that characterize respiratory distress. When the problem resides with the respiratory muscles (or their innervation), the same increase in neural output occurs (*arrow*), but the respiratory muscles cannot increase their effort as demanded; therefore, the physical signs of distress are more subtle. Finally, when the control of breathing is itself affected by disease, the neural response to hypoxemia and hypercapnia is absent or blunted and the gas exchange abnormalities are not accompanied by respiratory distress.

and failure. Reversing malnutrition, improving blood flow and substrate delivery, and correcting electrolyte abnormalities are therefore important steps to maintain the force-generating ability of the respiratory muscles and to delay respiratory failure. Such considerations are critical in chronic diseases, such as asthma, cystic fibrosis, and bronchopulmonary dysplasia, and in patients being weaned from prolonged ventilatory support.

CHRONIC RESPIRATORY FAILURE.

Independent of its etiology, the abnormalities in the arterial P_{O_2} and P_{CO_2} initiate a repertoire of physiologic responses directed at making the gas exchange derangement more tolerable for the patient. Most of these responses require days to weeks and, therefore, their detection in the physical or laboratory examinations indicates the chronic course of the failure. Arterial hypoxemia, for instance, induces a number of genes. The best characterized is the hypoxia-inducible factor-1 (HIF-1), a transcription factor implicated in the induction of a variety of other hypoxia-regulated genes. Among these is the erythropoietic factor, responsible for the development of polycythemia in patients with chronic arterial hypoxemia (although this may not be found in an infant or in a nutritionally impaired child). Other HIF-1–regulated genes include those encoding glycolytic enzymes, whose induction optimizes energy metabolism in the presence of reduced oxygen supply and angiogenesis (VEGF) and vasodilator factors (I-NOS), which activate biologic programs directed at raising the ability of tissues to extract oxygen from the blood.

Arterial hypercapnia stimulates H^+ secretion by the renal tubules, resulting in the addition of HCO_3^- ions to the extracellular fluid (approximately 3.5?mEq/L for every 10?mm Hg increment in the P_{CO_2}). The increase in the serum HCO_3^- levels returns the arterial pH toward normality (without ever normalizing it), lessens the decrease in arterial pH produced by a further rise in arterial P_{CO_2} , and reduces the stimulus for increased ventilation and the dyspnea associated with it. Infants and children with chronic respiratory failure may therefore depend on the stimulation of peripheral chemoreceptors by arterial hypoxemia to drive their breathing more than normal individuals, a feature that needs to be taken into account (but that does not contraindicate) in the administration of supplemental oxygen to these patients.

Clinical Manifestations.

The limited ability of the developing respiratory system to compensate for disease-induced mechanical abnormalities makes the early recognition of respiratory failure critical. Respiratory failure should be anticipated rather than recognized so that alterations in gas exchange can be prevented (see Chapter 57.3).

During physical examination, the clinician should avoid interfering with the patient's own mechanisms of compensation. An awake child with upper airway obstruction caused by croup or epiglottitis, for instance, may be more stable in a mother's arms because the increased gas flows and the increased forces generated during crying worsen the obstruction and can precipitate failure. Similarly, most patients with severe restrictive and obstructive disease tolerate the supine position poorly because it promotes gravity-dependent perfusion of

poorly ventilated areas and the weight of the abdominal organs imposes an additional burden on the diaphragm.

In a child suspected of respiratory failure, this evaluation should always start with a rapid assessment of the adequacy of ventilation, including the presence and vigor of the respiratory movements, breathing rate, the presence of cyanosis, and the presence of signs of upper airway obstruction (see Chapter 57.3). A child with grossly inadequate respiratory efforts or complete airway obstruction will die unless ventilation of the lungs is restored immediately. Special attention must be paid to the patient's state of consciousness. Hypoxemia and hypercarbia frequently cause lethargy and confusion, sometimes alternating with agitation. Whether resulting from these or other concurrent mechanisms, CNS depression requires immediate attention because it further limits the ability of the respiratory system to deal with mechanical loads and leaves the airway unprotected against obstruction and aspiration of foreign materials.

Acute hypoxemia and hypercapnia result in dilatation of the cerebral blood vessels and increased blood flow, often accompanied by severe headache. The sudden increased work of the accessory muscles of breathing may result in lower back pain. Although moderate to severe hypercapnia can cause peripheral vasodilation, mild to moderate hypoxemia can cause peripheral vasoconstriction, and the patient may have cold extremities, a finding that may divert attention toward a circulatory dysfunction when the main problem is respiratory. Other symptoms of hypoxia include restlessness, dizziness, and impaired thought.

Treatment.

The goal of treatment is the restoration of adequate gas exchange with a minimum of complications. This is achieved by eliminating the initiating factors as quickly as possible. Thus, respiratory failure caused by cardiogenic pulmonary edema is treated with inotropic medications and diuretics. The child with asthma should be managed with bronchodilators and anti-inflammatory medications. Unfortunately, even in acute illnesses such as these, the response to treatment is not immediate, and frequently the entire function of the respiratory system must be artificially supported (see also Chapter 57.4).

Hypoxemia is more dangerous than hypercarbia and may be easier to correct. Administration of supplemental oxygen is a safe and wise precaution in all patients at risk for respiratory failure, even if there is no initial evidence of hypoxemia. Oxygen can be administered with face masks, nasal cannulae, hoods, or tents. Face masks are usually not well tolerated by frightened infants and children. Hoods provide more consistent inspired oxygen concentrations than any other device, but they are bulky and limit access to the patient. For this reason, they have limited applicability in the initial treatment in the emergency department.

The indication for ventilatory support in a child with respiratory failure is usually based on the persistence or worsening of gas exchange (see Chapter 57.3 and Chapter 57.4). Mechanical ventilation is necessary in a child with pneumonia in whom severe hypoxemia and hypercarbia develops because even the most effective antibiotic therapy requires time. On occasion, ventilatory support must be instituted in the absence of alterations in the arterial P_{CO_2} when the dysfunction of other systems places gas exchange at jeopardy by limiting the compensatory ability of the respiratory system; cardiovascular shock is a typical example. In this latter condition,

decreased blood flow and substrate delivery to the respiratory muscles may reduce the force that these muscles can develop and can precipitate respiratory failure, even in the absence of substantial mechanical abnormalities of the respiratory system.

Ventilatory support often requires intubation of the trachea with an endotracheal tube or, less often, a tracheostomy cannula (see Chapter 57.3 and Chapter 57.4). Regardless of the type of ventilator, the objective of mechanical ventilation is not to normalize arterial blood gas tensions but rather to provide “adequate” gas exchange. The definition of what is “adequate” has changed substantially; some degree of hypercarbia and hypoxemia is acceptable to minimize oxygen- and stretch-induced lung injury of the lungs. Moderate hypercarbia (arterial P_{CO_2} of 60–80?mm Hg) has no detectable negative consequences over short periods, especially if the rise in P_{CO_2} is not very acute, in part because its effects on the arterial pH are eventually minimized through renal retention of bicarbonate. Moderate hypoxemia (oxygen saturation 85–90%) is similarly well tolerated in otherwise stable patients, particularly if the hemoglobin concentration and the cardiac output are maintained at physiologic values and conditions such as fever and agitation, which increase tissue oxygen demands, are avoided. Artificial-mechanical ventilation is usually initiated with conventional volume-driven ventilators; high-frequency jet or oscillator ventilators are often used as rescue therapy if conventional ventilators fail to improve oxygenation, but their efficacy is not proven in many circumstances (see Chapter 57.3 and Chapter 57.4).

Extracorporeal membrane oxygenation (ECMO) or carbon dioxide removal, or both, are employed in the treatment of newborns and small infants with life-threatening, refractory respiratory failure that is unresponsive to mechanical ventilation and is expected to resolve in a short time (see Chapter 90.7). Because of its risks (from vascular cannulation and anticoagulation) and the fact that its benefits over conventional management in non-neonatal patients have not been unequivocally demonstrated, indications for ECMO require considerable experience, caution, and judgment. Inhaled nitric oxide may acutely improve oxygenation by reducing increased pulmonary vascular resistance and has replaced the use of ECMO in many intensive care situations.

357.2 Congenital Central Hypoventilation Syndrome (Ondine Curse)

Gabriel G. Haddad

In children having congenital central hypoventilation syndrome (CCHS), there are usually no detectable *gross* anatomic abnormalities, although brainstem tumors and arteriovenous malformations have been described and other neurologic diseases must be considered. The primary defect is in the central nervous system (CNS), but there may also be abnormalities in other elements of the respiratory feedback loop (e.g., carotid bodies, peripheral chemosensitivity).

Pathogenesis and Pathophysiology.

The cause and pathogenesis of CCHS are unknown. Although there are reports of familial cases, the specific mode of inheritance is unknown. A rare association of Hirschprung disease was first described with Ondine curse in 1978 (Haddad syndrome). In one such case, a missense mutation in exon 12 of the *RET* proto-oncogene has been reported. Evaluation of the brain-derived neurotrophic factor (BDNF) genomic DNA sequence variation revealed that 1 in 19 children with CCHS screened for mutations in that gene showed a discrete mutation in BDNF; the unaffected father of the child showing the mutation also exhibited that mutation. Case control family studies have also shown that CCHS patients, their parents, and relatives were more likely to be affected than

---

controls and their parents and relatives in terms of an imbalance in the autonomic nervous system (ANS). The best-fitting genetic model of CCHS is that of a mendelian inheritance of a major gene disturbing the ANS.

Patients with CCHS or CCHS with Hirschsprung disease have no carbon dioxide sensitivity and no ventilatory response to carbon dioxide during sleep. During wakefulness, the carbon dioxide set point is much lower, and they respond to it, unless the condition is severe enough for hypoventilation to occur even in the awake state. These children also have been shown to have no sensitivity to hypoxia. This lack of sensitivity to carbon dioxide and the respiratory failure do not improve with time, and the oldest patients with CCHS still show the same failures. Older children with CCHS show an increase in ventilation when they are exercised at various work rates, and the increase in ventilation they exhibit may not be related to anaerobic stimuli (lactate or pH) but rather to neural reflexes (e.g., limb movements) or hormonal cues.

In CCHS, the condition expresses itself best during sleep, at which time sensory feedback plays a relatively minor role. The defect may be in the automatic control system, which resides mostly in the brainstem. Although physiologic evidence indicates that the respiratory failure in these children is mostly based on defects in central mechanisms, rather than on peripheral (carotid) mechanisms, the interactions between peripheral and central mechanisms also may be important. It is also important that premotor neurons, which communicate with phrenic or intercostal motor neurons, can be excited enough to drive the respiratory musculature in certain instances (e.g., wakefulness).

On postmortem examination of some CCHS patients, absence of the arcuate nucleus has been seen, but the relation of this anomaly to the disease is not clear. Gliosis in brainstem structures has also been noted, but this could be part of a more generalized response of the CNS to hypoxia and ischemia resulting from long-term

and intermittent respiratory failure.

Clinical Manifestations.

Patients with CCHS usually present early in life, often in the first few hours after delivery. Most children are the products of uneventful pregnancies and are term infants with appropriate weight for gestational age; Apgar scores have been variable. Symptoms of respiratory failure, with slow and irregular respiratory efforts, long respiratory pauses (lasting up to 40?sec), and cyanosis, appear in the first day of life. Cardiac, respiratory, infectious, and metabolic diseases, including intrauterine drug exposure, should be ruled out. One hallmark of this condition is that patients *fail* to respire adequately during sleep, not during wakefulness, although children with the most severe respiratory failure may hypoventilate in the waking state as well. In most neonates with CCHS, the Pa_{CO_2} accumulates to very high levels, sometimes up to 80–90?mm Hg, during sleep and drops to normal levels soon after the infants awaken. Infants in the first few weeks of life have been shown to have long respiratory pauses, a relatively normal tidal volume, and a very low respiratory rate (dropping to as low a level as 8–10 breaths/min during sleep) with interspersed respiratory pauses. Respiratory rates are generally normal during wakefulness, and the lowest respiratory rates have been found in non–rapid eye movement or quiet sleep.

Because respiratory failure in these infants has a central cause, the hypoxemia that ensues is commensurate with hypoventilation with little or no abnormality in the arterial-alveolar (A-a) gradient. However, in some children, the hypoventilation may be severe enough to produce airway closure, microatelectasis, and an increase in the A-a gradient.

In a sizable subset of these infants, abdominal distention, constipation, or complete failure to pass meconium occurs. Rarely, a child with CCHS also has diagnosed Hirschsprung disease with variable aganglionosis of the colon and small intestine. Whether all patients with congenital CCHS have some degree of aganglionosis of the large bowel is unknown.

Patients with CCHS also have a faster heart rate than normal for their age and low heart rate variability, an almost fixed heart rate with little sinus arrhythmia. Other anomalies found on autopsy suggesting abnormalities in the autonomic regulation of vital functions include multiple ganglioneuroblastomas of the sympathetic chain and the adrenal medulla.

Differential Diagnosis.

Other neurologic diseases or conditions have to be excluded before this diagnosis is made. Brainstem infarction, tumors, arteriovenous malformations, syringomyelia, Leigh necrotizing encephalomyelopathy, olivopontocerebellar degeneration, and Möbius syndrome should be considered.

Treatment.

Management should include general and nutritional care, ventilatory support, and prevention of acidosis, cerebral hypoxia, and ischemia. Some of these infants can grow and gain developmental and neurologic milestones that are close to normal for age, although hypoventilation abnormalities persist. These abnormalities may be a result of episodes of hypoxia or part of the spectrum of CCHS. Attempts at pharmacologic respiratory stimulation have been unsuccessful.

Phrenic nerve pacing has been used in patients after the age of 2 yr. Although there are complications related to pacing, including phrenic nerve fibrosis, infections, and multiple surgeries, a number of these patients have eventually become independent of mechanical ventilators.

Chapter 358 - Defense Mechanisms and Metabolic Functions of the Lung

Gabriel G. Haddad
J. Julio Pérez Fontán

358.1 Defense Mechanisms

Overview.

Effective and multiple defense mechanisms in the lungs are especially important because the respiratory system is constantly exposed to a changing and often “polluted” environment containing irritants, pathogens, and allergens. The defense system is composed of three limbs: (1) the cough reflex, which relies on the integrity of the airways, (2) the respiratory muscles, and (3) the central nervous system control centers. The

cilia and mucociliary apparatus rely on the morphologic and functional integrity of the cilia and the respiratory epithelium (see Chapter 394). The mechanical defenses of the respiratory system that protect the lung include the filtering of particles, the warming and humidification of inspired air, and the absorption of noxious fumes and gases by the vascular upper airway. The temporary cessation of breathing, reflexly shallow breathing, laryngospasm, or even bronchospasm limits the depth and amount of penetration of foreign matter. Spasm or decreased breathing can provide only brief protection. Cough also is an important mechanism. Aspiration of food, secretions, and foreign bodies is prevented by swallowing and closure of the epiglottis. The respiratory tract distal to the larynx is normally sterile. The immune system is important in determining the propensity of individuals to lung infections.

The *upper airway* includes the nose, paranasal sinuses, and pharynx; the *lower airway* consists of the remainder of the system from the larynx peripherally. The nose has a relatively large surface area lined with a richly vascular, ciliated epithelium; and by the time the air column reaches the bifurcation of the trachea, up to 75% of the warming and humidification of the inspired air has occurred. During exhalation, heat and moisture are removed from the air stream. Gross filtering of particles larger than 10–15?mm is achieved by the coarse hairs at the nasal orifices, and most inhaled particles larger than 5?mm are impacted on the nasal surface (see Section 2).

Because the larynx is relatively narrow and ringed with cartilage, it is relatively susceptible to obstruction in young children, particularly by inflammation, because the resultant swelling of tissues rapidly encroaches on the lumen and produces inspiratory stridor.

The trachea and bronchi are lined with pseudostratified, ciliated, columnar epithelium and occasional goblet cells. Mucous glands occupy approximately one third of the thickness of the airway wall and for the most part lie between the epithelial surface and the cartilage. The trachea is supported by incomplete rings of cartilage with a muscular membrane posteriorly. Irregular plates of cartilage support the bronchi, especially at bifurcations. These diminish and finally disappear in the smallest bronchi. The goblet cells and principally the submucosal glands secrete the mucous layer, which is 2–5?mm in depth and rests on the tips of the cilia. Each ciliated cell has about 275 cilia; movement results from action by microtubules within each cilium. The cilia beat within a periciliary fluid layer at about 1,000 beats/min, moving the mucous blanket toward the pharynx at a rate of approximately 10?mm/min in the trachea. In the respiratory portion of the lung, the surface cells gradually become cuboidal and then flat; ciliated cells and goblet cells are usually absent.

The final 25% of the warming and humidifying of the inspired air stream occurs in the trachea and large bronchi. Failure of humidification permits dry air to reach more distal airways. Particles 1–5?mm in size precipitate out on the tracheobronchial mucous blanket so that only particles of 1?mm or less reach the respiratory bronchioles and air spaces, where some may deposit and many will be exhaled.

Respiratory tract secretions are derived primarily from mucous (glycoproteins) and serous cells of the submucosal glands that empty onto the surface epithelium; from goblet cells and Clara cells, the special secreting cells in the surface epithelium of bronchi and bronchioles, respectively; from transudation from the vascular space; and from alveolar fluid, which contributes most of the phospholipid found in tracheobronchial mucus. This mucus is about 95% water.

Beyond infancy, collateral alveolar ventilation can occur increasingly with development of the *pores of Kohn* between alveoli, which provide a means for gas to pass from one lobule to another, perhaps even between segments of lung. Bronchiolar-alveolar communications, known as the *canals of Lambert*, are also found. These anatomic connections may be helpful in preventing or delaying atelectasis.

Clearance of Particles.

Particles deposited in conducting airways are cleared within hours by the mucociliary mechanism, whereas clearance of those reaching the alveoli may take several days to months. The latter may be phagocytized by alveolar macrophages and removed from lungs by the mucociliary system or carried into the interstitium for clearance by the lymphocytes into regional nodes or the blood. Some particles penetrate into the

interstitium without phagocytosis. Mucociliary clearance may be aided by cough, which propels excess mucus up the airways at high pressures and flows.

Cough is characterized by four specific phases: (1) a very deep and rapid inspiratory effort, having the effect of achieving a high and optimal thoracic volume for the subsequent phases of the cough; (2) compression, which is characterized by closure of the glottis, activation of the diaphragm and chest wall muscles and, consequently, compression and building of pleural, alveolar, and abdominal pressures; (3) expression of the cough marked by a sudden opening of the glottis, high expiratory airflow, and an explosive sound; and (4) relaxation of the musculature and reversal of pressures. Although such events occur in the characteristic cough, they may not occur in every cough.

The effect of cough on mucus clearance depends on a number of factors. These are the gas-fluid interactions, the rheology of mucus, the respiratory pattern, and the cough pump structure. With very “slow” airflows, air is so sluggish that it moves through mucus without affecting its transport. This occurs during obstructive disease and when the nature of the mucus is affected by inflammation, debris, cellular material, and increased amount of secretion. Higher airflows can, on the other hand, be very effective. The rheology of mucus is important; consider for instance the severe viscous and highly elastic nature of the secretions in cystic fibrosis. The breathing pattern is also critical because the higher the volume inspired and the shorter the expiratory time, the higher the airflow and the higher the probability for the cough to clear secretions. Moreover, because the strength of cough depends on the structure of the airways and their integrity, airway pathology will affect the strength of the cough. For example, any exaggerated collapse of the airways during expiration severely limits the forcefulness of the cough, as occurs with tracheomalacia in the premature, tracheal stenosis, and extrinsic compression of the airways. Cough can also be jeopardized when respiratory muscles do not generate the necessary pressures (i.e., weak, paralyzed, fatigued) and when the airways cannot be well splinted.

Defense Against Microbial Agents.

Phagocytosis and mucociliary clearance may not be sufficient protection from living agents, such as bacteria and viruses. Additional factors include cellular killing of organisms and immune responses to assist in the phagocytosis-killing process. Alveolar and interstitial macrophages, derived from monocytes, are an essential component of the defense system of the lung. The engulfment and killing of living particles by these macrophages may be enhanced by opsonins or by small lymphocytes. The principal antibody in respiratory secretions is secretory IgA, which is produced by plasma cells in the submucosa of the airways (see Chapter 114.3) and is highly resistant to digestion by proteolytic enzymes released after lysis of bacteria and dead cells. IgA can neutralize certain viruses and toxins and helps in the lysis of bacteria. IgA may also prevent antigenic substances from penetrating the epithelial surfaces. Pulmonary secretory IgA reaches adult levels in the first month of life. IgG and IgM are also found in the secretions when lung inflammation occurs.

Lysozyme, lactoferrin, and interferon may also play a defensive role in respiratory secretions. In addition, a small fraction of the antibodies of the respiratory surface is made up of IgE,

which plays an important role in allergic reactions (see Chapter 130).

The phagocytic ability of alveolar macrophages and, in most cases, the mucociliary mechanism can be impaired by ethanol ingestion, cigarette smoke, hypoxemia, starvation, chilling, corticosteroids, nitrogen dioxide, ozone, increased oxygen concentration, narcotics, and some anesthetic gases. The antibacterial killing capacity of the macrophages can be decreased by acidosis, azotemia, and recent acute viral infections, especially rubeola and influenza. Beryllium and asbestos, organic dust from cotton and sugar cane, and gases such as sulfur, nitrogen dioxide, ozone, chlorine, ammonia, and cigarette smoke are toxic to epithelial cells.

Mucociliary clearance can be reduced by hypothermia, hyperthermia, morphine, codeine, and hypothyroidism. Inhalation of dry gas by mouth breathing during periods of nasal obstruction, after performance of a tracheostomy, or during use of poorly humidified oxygen results in drying of the mucous membranes and slowing of the ciliary beat. Cold air may irritate the tracheobronchial tree.

Damage to the respiratory epithelium may be reversible with rhinitis, sinusitis, bronchitis, bronchiolitis, acute respiratory infections associated with high levels of air pollution, and the epithelial shedding that can occur in asthma, or with some irritants, bronchospasm, edema, congestion, and perhaps mild surface ulceration. However, severe ulceration, bronchiectasis, bronchiolectasis, squamous cell metaplasia, and fibrosis may cause serious injury and permanent impairment of the normal clearance mechanism. Other events that can adversely affect the lung include hyperventilation, alveolar hypoxia, pulmonary thromboembolism, pulmonary edema, hypersensitivity reactions, and certain drugs, such as salicylates.

358.2 Metabolic Functions

The lung contains more than 40 separate cell types; the type I and II pneumocytes, alveolar macrophages, and Clara cells are unique to the lung. The lung can synthesize lipids and proteins, including glycoproteins, secretory antibodies, interferon, proteolytic and fibrinolytic enzymes and activators, collagen, and elastin. Tissue factors such as thromboplastin are found in higher concentration in the lung than in any other organ. Megakaryocytes are concentrated in the lung.

The large alveolar type II pneumocyte synthesizes and releases lung surfactant. Injury to this cell or deficiency in this surfactant pathway results in neonatal

respiratory distress syndrome and other disorders (see Chapter 90.3 , Chapter 396 , and Chapter 397). A major function of surfactant is to stabilize alveolar air spaces by attenuating surface forces and decreasing their unevenness. Another cell type, the neuroepithelial cell, is present at the airway bifurcation and is found in larger proportion in early life. These cells are serotonin-rich and have transmitter vesicles that are depleted when exposed to low inhaled oxygen concentration. These cells sense oxygen in the airways through plasma membrane K^+ channels and can send afferent information to the central nervous system via the vagus nerve.

Because the lung has the only capillary bed through which the entire blood flow must pass in the normal state, the pulmonary capillary circulation is ideally positioned to control circulating vasoactive hormones. Angiotensin II, up to 50 times more active than its precursor, is converted from angiotensin I during one passage through the pulmonary circulation. Some vasoactive materials, including serotonin, bradykinin, adenosine triphosphate, and prostaglandins E_1 , E_2 , and F_2 , are almost completely removed or inactivated by one passage through the pulmonary circulation, whereas others, such as epinephrine, prostaglandins A_1 and A_2 , angiotensin II, and vasopressin, may be minimally affected. Norepinephrine and histamine are taken up to a moderate degree. Failure of inactivation or periodic release of substances such as serotonin, bradykinin, histamine, slow-reacting substance of anaphylaxis (SRS-A), eosinophil chemotactic factor, platelet aggregation factor, endocrine substances, and so forth, may be important in the pathogenesis of some pulmonary diseases or as mediators of secondary effects. These chemicals can contribute to systemic and pulmonary hypertension, systemic hypotension, and pulmonary edema.

The lung epithelium is also endowed with a variety of receptors and membrane proteins that are important for processes such as lung fluid absorption in early life and after lung injury or infections. The epithelium indeed has many channel species: the cystic fibrosis transmembrane conductance regulator, Na^+ and K^+ channels, exchangers (e.g., Na^+ -K^+ ATPase, Na^+ / K^+ /2Cl^- , Na^+ /H^+), and other membrane proteins such as aquaporins. Dopamine agonists, working through dopamine D_1 receptors, seem also to be involved in enhancing the expression of the Na^+ -K^+ ATPase on the plasma membrane and hence increasing the ability of the alveolar epithelial cells to absorb fluids. High-altitude edema may also involve Na^+ -dependent proteins because the expression of these is generally decreased in cells exposed to low O_2 conditions.

Chapter 359 - Diagnostic Approach to Respiratory Disease

Gabriel G. Haddad
Regina M. Palazzo

The history and physical examination are the most important first steps in diagnosing respiratory disease. The observed signs and symptoms significantly influence the direction of the subsequent investigations.

History.

Family and personal histories are essential for interpreting physical findings and diagnosing respiratory system disease. The history should include questions about respiratory symptoms, their chronicity, their timing during day or night, and whether they are associated with any activity such as exercise or food intake. In addition, the respiratory system interacts with a number of other systems, and questions related to cardiac, gastrointestinal, central nervous system, hematologic, and immune systems may be relevant. For example, questions related to gastrointestinal reflux or immune status may be important in a patient with repeated pneumonias.

Physical Examination.

Respiratory dysfunction usually produces detectable alterations in the pattern of breathing. Values for normal respiratory rates are presented in Table 57–1 and depend on many factors, including age. It is important at the bedside not to be satisfied with one respiratory rate measurement because respiratory rates, especially in the young, are exquisitely sensitive

to extraneous stimuli. These rates vary among infants but average 40–50 breaths/min in the first weeks of life and usually less than 60 breaths/min in the first few days of life. Respiratory control abnormalities may cause the child to breathe at a low rate or periodically. Mechanical abnormalities produce compensatory changes that are generally directed at maintaining or increasing ventilation. These changes include variable increases in the breathing rate, chest wall retractions, and nasal flaring. Children with restrictive disease breathe at faster rates, and their respiratory excursions are shallow. An expiratory grunt is common as the child attempts to raise the functional residual capacity (FRC) by closing the glottis at the end of expiration. Children with obstructive disease take slower, deeper breaths. When the obstruction is extrathoracic (from the nose to the midtrachea), inspiration is more prolonged than is expiration, and an inspiratory stridor can usually be heard. When the obstruction is intrathoracic, expiration is more prolonged than is inspiration, and the patient often has to make use of accessory expiratory muscles. Lung percussion is usually dull in restrictive lung disease and tympanitic in obstructive disease but has limited value in small infants because it cannot discriminate between noises originating from tissues that are close to each other. Auscultation confirms the presence of inspiratory or expiratory prolongation and provides information about the symmetry and quality of air movement. In addition, it often detects abnormal or adventitious sounds such as *stridor* (a predominant inspiratory monophonic noise), *rales* or *crackles* (high pitch, interrupted sounds found during inspiration and more rarely during early expiration, which denote opening of previously closed air spaces), or *wheezes* (musical, continuous sounds usually caused by the development of turbulent flow in narrow airways).

Blood Gas Analysis.

An arterial blood gas analysis is probably the single most useful test of pulmonary function. Because cyanosis is influenced by skin perfusion and blood hemoglobin concentration, it is an unreliable sign of hypoxemia. Arterial hypertension, tachycardia, and diaphoresis are late, and by no means exclusive, signs of hypoventilation. Blood gas exchange is evaluated most accurately by the *direct* measurement of arterial P_{O_2} , P_{CO_2} , and pH (see Chapter 55 and Chapter 90.3). The blood specimen is best collected *anaerobically* in a heparinized syringe containing only enough heparin solution to displace the air from the syringe. The syringe should be sealed, placed in ice, and carried to the laboratory for immediate analysis. Although these measurements have no substitute in many conditions, they require arterial puncture and have been replaced to a great extent by noninvasive monitoring.

The age and clinical condition of the patient need to be taken into account when interpreting blood gas tensions. With the exception of neonates, values of arterial P_{O_2} lower than 85?mm Hg are usually abnormal for a child breathing room air at sea level. Calculation of the alveolar-arterial oxygen gradient is useful in the analysis of arterial oxygenation, particularly when the patient is not breathing room air or in the presence of hypercarbia. Values of arterial P_{CO_2} exceeding 45?mm Hg usually indicate hypoventilation or a severe ventilation-perfusion mismatch, unless they reflect respiratory compensation for metabolic alkalosis (see Chapter 45).

Transillumination of the Chest.

In infants up to at least 6 mo of age, a pneumothorax may often be diagnosed by transillumination of the chest wall using a fiberoptic light probe. Free air in the pleural space often results in an unusually large halo of light in the skin surrounding the probe. This test is unreliable in older patients or in those with subcutaneous

emphysema or atelectasis.

RADIOGRAPHIC TECHNIQUES

Chest Roentgenograms.

Whenever possible, a posteroanterior and a lateral view (upright and in full inspiration) should be obtained. Portable films, although useful, may give a somewhat distorted image. Expiratory films may easily be misinterpreted, although a comparison of expiratory and inspiratory films may be useful in the evaluation of a child with suspected foreign body (localized failure of the lung to empty reflects bronchial obstruction). If pleural fluid is suspected, decubitus films are indicated. Films taken in a recumbent position are difficult to interpret if there is fluid within the pleural space or a cavity.

Upper Airway Films.

A lateral view of the neck can yield invaluable information about upper airway obstruction and particularly about the condition of the retropharyngeal, supraglottic, and subglottic spaces (which should also be viewed in an anteroposterior projection). Knowing the phase of respiration during which the film was taken is often essential for accurate interpretation. Magnified airway films are often helpful in delineating the upper airways. Patients with suggested obstruction should not be sent unattended to the radiology department.

Sinus and Nasal Films.

Roentgenographic examination of the sinuses is indicated when sinus disease is suspected. A coronal CT scan gives the most information. Because of the small size and slow development of the frontal and maxillary sinus cavities in children, transillumination is not as successful in documenting sinus disease as are roentgenograms. Sinus roentgenograms are particularly useful in patients with suspected continuous sinus infection. The need for examining the nasal passages in children is unusual and occurs most often when the neonate presents with obstruction or when a tumor or occult foreign body is suggested.

CT and MRI.

CT delineates the internal structure of the thorax in much greater detail than is possible with plain roentgenograms. Technical advances have greatly enhanced the utility of this diagnostic modality (three-dimensional reconstruction is often feasible), whereas scan times and radiation exposure have been markedly reduced. CT scans are of particular importance in the evaluation of mediastinal and pleural lesions, solid or cystic parenchymal lesions, and suggested bronchiectasis. Intravenous contrast material can be infused during the scan to enhance vascular structures.

MRI may be useful for the same disease entities as CT. MRI is an excellent procedure to delineate hilar and vascular anatomy associated with vascular rings or slings.

Fluoroscopy.

Fluoroscopy is especially useful for evaluating stridor and abnormal movement of the diaphragm or mediastinum. Many procedures, such as needle aspiration or biopsy of a peripheral lesion, are also best accomplished with the aid of fluoroscopy. Videotape recording, which does not increase radiation exposure, may allow detailed study through “replay” capability during a brief exposure to fluoroscopy.

Contrast Studies

BARIUM SWALLOW.

This study, performed with fluoroscopy and spot films, is indicated in the evaluation of patients with recurrent pneumonia, persistent cough of undetermined cause, stridor, or persistent wheezing. The technique may be modified by using barium of different textures and thicknesses, ranging from thin liquid to solids, to evaluate swallowing mechanics, the presence of vascular rings, and tracheoesophageal fistulas, especially when aspiration is suspected. A contrast esophagram has been used in the evaluation of newborns with suggested esophageal atresia, but this procedure entails a high risk of pulmonary aspiration and is not usually recommended. Barium swallows are useful in the evaluation of suggested gastroesophageal reflux, but the interpretation may not be straightforward.

BRONCHOGRAMS.

The details of smaller bronchi that cannot be easily evaluated by plain films or even bronchoscopy may

be delineated by instilling contrast material directly into the airway. This is indicated in patients with suspected bronchiectasis or airway anomalies who may need surgery, although CT and MRI have largely supplanted bronchography, which requires sedation and topical anesthesia, or even general anesthesia.

PULMONARY ARTERIOGRAMS.

These studies allow detailed evaluation of the pulmonary vasculature and are helpful in assessing pulmonary blood flow and in diagnosing congenital anomalies, such as lobar agenesis, unilateral hyperlucent lung, vascular rings, and arteriovenous malformations and are sometimes useful in evaluating solid or cystic lesions. Real-time and Doppler echocardiography are noninvasive methods that often reveal similar information and should be performed before arteriography.

AORTOGRAMS.

Thoracic aortograms demonstrate the aortic arch and its major vessels and the

systemic (bronchial) pulmonary circulation. They are useful in evaluating vascular rings and suspected pulmonary sequestration. Although most hemoptysis is from the bronchial arteries, bronchial arteriography is seldom helpful in diagnosing or treating intrapulmonary bleeding in children. Echocardiography with or without CT or MRI is helpful in delineating some of these lesions and should be performed before aortography.

PNEUMOPERITONEUM AND PNEUMOTHORAX.

In selected situations, such as in the evaluation of diaphragmatic eventration, it may be advantageous to inject a small amount of air into the pleural or peritoneal cavity, outlining the limits of the diaphragm or pleural surfaces by air contrast. Rapidly absorbed, the air causes no functional impairment.

RADIONUCLIDE LUNG SCANS.

The usual scan uses intravenous injection of material (macroaggregated human serum albumin labeled with ^{99m} Tc) that will be trapped in the pulmonary capillary bed. The distribution of radioactivity, proportional to pulmonary capillary blood flow, is useful in evaluating pulmonary embolism and congenital cardiovascular and pulmonary defects. Acute changes in the distribution of pulmonary perfusion may reflect alterations of pulmonary ventilation.

The distribution of pulmonary ventilation also may be determined by scanning after the inhalation of a radioactive gas such as xenon-133. After the intravenous injection of xenon-133 dissolved in saline, both pulmonary perfusion and ventilation can be evaluated by continuous recording of the rate of appearance and disappearance of the xenon over the lung. Appearance of xenon early after injection is a measure of perfusion, whereas the rate of washout during breathing is a measure of ventilation in the pediatric population. The most important indication for this test is to demonstrate defects in the pulmonary arterial distribution that may occur with congenital malformations or pulmonary embolism. Spiral reconstruction CT with contrast medium enhancement is being increasingly used in the evaluation of pulmonary thrombi and emboli. Abnormalities in regional ventilation are also easily demonstrable in congenital lobar emphysema, cystic fibrosis, and asthma.

PULMONARY FUNCTION TESTING

Overview.

The measurement of respiratory function in infants and young children may be difficult because of the lack of cooperation. Attempts have been made to overcome this limitation by creating standard tests that do not require the patient's active participation. Respiratory function tests still provide only a partial insight into the mechanisms of respiratory disease at early ages.

Whether restrictive or obstructive, most forms of respiratory disease cause alterations in lung volume and its subdivision (see Fig. 357–2). Restrictive diseases typically decrease total lung capacity (TLC). TLC includes residual volume, which is not accessible to direct determinations. It must therefore be measured indirectly by gas dilution methods or, preferably, by plethysmography. Restrictive disease also decreases vital capacity (VC). VC can be measured by spirometry and is commonly used at the bedside to assess the progression of neuromuscular disorders. Obstructive diseases produce gas trapping and thus increase residual volume and FRC, particularly when these measurements are considered with respect to TLC.

Airway obstruction is most frequently evaluated from determinations of gas flow in the course of a forced expiratory maneuver. The peak expiratory flow is reduced in advanced obstructive disease. The wide availability of simple devices that perform this measurement at the bedside makes it useful for assessing children with airway obstruction. Evaluation of peak flows requires a voluntary effort, and peak flows may not be altered when the obstruction is moderate or mild. Other gas flow measurements require that the child inhale to TLC and then exhale as far and as fast as possible for several seconds. Cooperation and good muscle strength are therefore necessary for the measurements to be reproducible. The forced expiratory volume in 1?sec (FEV_1) correlates well with the severity of obstructive diseases. The maximal midexpiratory flow rate, the average flow greater than the middle 50% of the forced vital capacity, is a more reliable indicator of mild airway obstruction. Its sensitivity to changes in residual volume and vital capacity, however, limits its use in children with more severe disease. The construction of flow-volume relationships during the forced vital capacity maneuvers overcomes some of these limitations by expressing the expiratory flows as a function of lung volume (see Chapter 357).

Practical Issues.

A *spirometer* is used to measure VC and its subdivisions and expiratory (or inspiratory) flow rates (see Fig. 357–2). A simple *manometer* can measure the maximal inspiratory and expiratory force a subject generates, normally at least 30?cm H_2O, which is useful in evaluating the neuromuscular component of ventilation. Expected normal values for VC, FRC, TLC, and residual volume are obtained from prediction equations based on body height.

Flow rates measured by spirometry usually include the FEV_1 and the maximal midexpiratory flow rate. More information results from a maximal expiratory flow-volume curve, in which expiratory flow rate is plotted against expired lung volume (expressed in terms of either VC or TLC). Flow rates at lung volumes less than about 75% VC are relatively independent of effort. Expiratory flow rates at low lung volumes (less than 50% VC) are influenced much more by small airways than are flow rates at high lung volumes (FEV_1). The flow rate at 25% VC (V_{25}) is a useful index of small airway function. Low flow rates at high lung volumes associated with normal flow at low lung volumes suggest upper airway obstruction (see Chapter 356 and Chapter 357).

Airway resistance (R_{AW}) is measured in a plethysmograph and is expressed as centimeters of water/liter/second. Alternatively, the reciprocal of R_{AW} , *airway conductance* (G_{AW}), may be used. Because airway resistance measurements vary with the lung volume at which they are taken, it is convenient to use specific airway resistance, SR_{AW} ($SR_{AW} = R_{AW}$ /lung volume), which is nearly constant in subjects older than 6 yr (normally less than 7?sec/cm H_2O).

The *diffusing capacity for carbon monoxide* is related to oxygen diffusion and is measured by rebreathing from a container having a known initial concentration of carbon monoxide or by using a single breath technique. Decreases in diffusing capacity for carbon monoxide reflect decreases in effective alveolar capillary surface area or decreases in diffusibility of the gas across the alveolar-capillary membrane. Primary diffusion abnormalities are unusual in children; therefore, this test is most frequently employed in children exposed to toxic drugs to the lungs (e.g., oncology patients) or chest wall radiation. *Regional gas exchange* may be conveniently estimated with the perfusion-ventilation

xenon scan. Determining *arterial blood gas* levels also disclose the effectiveness of alveolar gas exchange (see earlier).

Clinical Uses.

Pulmonary function testing, although rarely resulting in a diagnosis, is helpful in *defining the type of process* (e.g., obstruction, restriction) and the *degree of functional impairment,* in *following the course and treatment of disease,* and in *estimating the prognosis*. It is also useful in *preoperative evaluation* and in confirmation of functional impairment in patients having subjective complaints but a normal physical examination. In most patients with obstructive disease, a repeat test after administering a bronchodilator is warranted.

Most tests require some cooperation and understanding by the patient, and interpretation is greatly facilitated if the test conditions and the patient's behavior during the test are known. Accurate testing of children aged 3–6 yr requires great patience by the physician and training of the patient, whereas most children aged 6 yr or older can be tested reliably without excessive difficulty. Infants and young children who cannot or will not cooperate with test procedures can be studied in a limited number of ways, which often require sedation. Flow rates and pressures during tidal breathing, with or without transient interruption of the flow, may be useful to assess some aspects of airway resistance or obstruction and to measure compliance of the lungs and thorax. Expiratory flow rates may be studied in sedated infants with passive compression of the chest and abdomen with a rapidly inflatable jacket. Gas dilution or plethysmographic methods may also be used in sedated infants to measure FRC and R_{AW} .

MICROBIOLOGY: EXAMINATION OF SECRETIONS

The specific diagnosis of infection in the lower respiratory tract depends on the proper handling of an adequate specimen obtained in an appropriate fashion. Nasopharyngeal or throat cultures are often used but may not correlate with cultures obtained by more direct techniques from the lower airways. Sputum specimens are preferred and are often obtained from patients who do not expectorate by deep throat swab immediately after coughing. Specimens may also be obtained directly from the tracheobronchial tree by nasotracheal aspiration (usually heavily contaminated), by transtracheal aspiration through the cricothyroid membrane (useful in adults and adolescents but hazardous in children), and in infants and children by a sterile catheter inserted into the trachea either during direct laryngoscopy or through an endotracheal tube. A specimen also may be obtained at bronchoscopy. A percutaneous lung tap or an open biopsy is the only way to obtain a specimen that may be absolutely free of oral flora.

A specimen obtained by direct expectoration is usually assumed to be of tracheobronchial origin, but often, especially in children, it is not from this source. The presence of alveolar macrophages—large, mononuclear cells—is the hallmark of tracheobronchial secretions. Both nasopharyngeal and tracheobronchial secretions may contain ciliated epithelial cells, which are more commonly found in sputum. Nasopharyngeal and oral secretions often contain large numbers of squamous epithelial cells. Sputum may contain both ciliated and squamous epithelial cells.

During sleep, mucociliary transport continually brings tracheobronchial secretions to the pharynx, where they are swallowed. An early morning fasting gastric aspirate often contains material from the tracheobronchial tract that is suitable for culture for acid-fast bacilli.

The absence of polymorphonuclear leukocytes in a Wright-stained smear of sputum or bronchoalveolar lavage (BAL) fluid containing adequate numbers of macrophages may be significant evidence against a bacterial infectious process in the lower respiratory tract, assuming that the patient has normal neutrophil counts and function. Eosinophils suggest allergic disease. Iron stains may reveal hemosiderin granules within macrophages, suggesting pulmonary hemosiderosis. Specimens should also be examined by Gram stain. Bacteria within or near macrophages and neutrophils can be significant. Viral pneumonia may be accompanied by intranuclear or cytoplasmic inclusion bodies visible on Wright-stained smears, and fungal forms may be identifiable on Gram or silver stains.

EXERCISE TESTING

Exercise testing (also see Chapter 416.5) is a more direct approach for detecting diffusion impairment as well as other forms of respiratory disease. Measurements of heart and respiratory rate, minute ventilation, oxygen consumption, carbon dioxide production, and arterial blood gases during incremental exercise loads often provide invaluable information about the functional nature of the disease. Often a simple assessment of the patient's exercise tolerance in conjunction with other more static forms of respiratory function testing may allow a distinction between respiratory and nonrespiratory disease in children.

SLEEP STUDIES

The sleep state has an important influence on respiratory function, particularly in the newborn and young infant. Polysomnographic studies are often helpful when abnormalities of central respiratory control, muscular disorders, or respiratory complications from gastroesophageal reflux are suspected. For the latter condition, pH probe studies are indicated in which a pH probe is placed in the esophagus and prolonged (usually over several hours) monitoring is undertaken (see Chapter 304).

These studies, which usually include the simultaneous assessment of ventilatory effort, airway gas flow, gas exchange, and sleep state, are also useful in the diagnosis and management of nocturnal hypoxemia and hypercarbia in children with chronic respiratory disease (see Chapter 357.2).

LUNG VISUALIZATION AND LUNG SPECIMEN–BASED DIAGNOSTIC TESTS

Endoscopy

LARYNGOSCOPY.

The evaluation of stridor, problems with vocalization, and other upper airway abnormalities usually require direct inspection. Although indirect (mirror) laryngoscopy may be reasonable in older children and adults, it is rarely feasible in infants and small children. Direct laryngoscopy may be performed with either a rigid or a flexible instrument. The safe use of the rigid scope for examination of the upper airway requires topical anesthesia and either sedation or general anesthesia, whereas the flexible laryngoscope can often be used in the office setting with or without sedation. Further advantages to the flexible scope include the ability to assess the airway without the distortion that may be introduced by the use of the rigid scope and the ability to assess airway dynamics more accurately. Because there is a relatively high incidence of concomitant lesions in the upper and lower airways, it is often prudent to examine the airways above and below the glottis, even when the primary indication is in the upper airway (stridor).

BRONCHOSCOPY AND BRONCHOALVEOLAR LAVAGE (BAL).

Bronchoscopy is the inspection of the airways. BAL is a method used to obtain a representative specimen of fluid and secretions from the lower respiratory tract, which is useful for the cytologic and microbiologic diagnosis of lung diseases, especially in those who are unable to expectorate sputum. Commonly, BAL is performed after the general inspection of the airways and before tissue sampling with a brush or biopsy forceps. BAL is accomplished by gently wedging the scope into a lobar, segmental, or subsegmental bronchus and sequentially instilling and withdrawing sterile nonbacteriostatic saline in a

volume sufficient to ensure that some of the aspirated fluid contains material that originated from the alveolar space. Nonbronchoscopic BAL can be performed in intubated patients by instilling and withdrawing saline through a catheter passed though the artificial airway and blindly wedged into a distal airway. In either case, the presence of alveolar macrophages documents that an alveolar sample has been obtained. Because the methods used to perform BAL involve passage of the equipment through the upper airway, there is a risk of contamination of the specimen by upper airway secretions. Careful cytologic examination and quantitative microbiologic cultures are important for correct interpretation of the data. BAL can often obviate the need for more invasive procedures such as open lung biopsy, especially in immunocompromised individuals.

Indications for diagnostic bronchoscopy and BAL include recurrent or persistent pneumonia or atelectasis, unexplained or localized and persistent wheeze, the suspected presence of a foreign body, hemoptysis, suspected congenital anomalies, mass lesions, interstitial disease, and pneumonia in the immunocompromised host. Indications for therapeutic bronchoscopy and BAL include bronchial obstruction by mass lesions, foreign bodies or mucus plugs, and general bronchial toilet and bronchopulmonary lavage. The individual undergoing bronchoscopy ventilates around the flexible scope, whereas with the rigid scope ventilation is accomplished through the scope. Rigid bronchoscopy is preferentially indicated for the extraction of foreign bodies and the removal of tissue masses and in patients with massive hemoptysis. In other cases, the flexible scope offers the advantages that it can be passed through endotracheal or tracheostomy tubes, can be introduced into bronchi that come off the airway at acute angles, and can be safely and effectively inserted with topical anesthesia and conscious sedation.

Regardless of the instrument used, the procedure performed, or its indications, the most common *complications* are related to sedation. The relatively more common complications include transient hypoxemia, laryngospasm, bronchospasm, and cardiac arrhythmias. Iatrogenic infection, bleeding, pneumothorax, and pneumomediastinum are rare but reported complications of bronchoscopy or BAL. Subglottic edema is a more common complication of rigid bronchoscopy than of flexible procedures, in which the scopes are smaller and less likely to traumatize the mucosa. Postbronchoscopy croup is treated with oxygen, mist, vasoconstrictor aerosols, and corticosteroids as necessary.

THORACOSCOPY.

The pleural cavity may be examined through a thoracoscope, which is similar to a rigid bronchoscope. The thoracoscope is inserted through an intercostal space and the lung is partially deflated, thus allowing the operator to view the surface of the lung, the pleural surface of the mediastinum and diaphragm, and the parietal pleura. Multiple thoracoscopic instruments can be inserted, allowing endoscopic lung or pleural biopsy, bleb resection, pleural abrasion, and ligation of vascular rings.

Purcutaneous Taps

THORACENTESIS.

For diagnostic or therapeutic purposes, fluid may be removed from the pleural space by needle. Generally, as much fluid as possible should be withdrawn, and an *upright* chest roentgenogram should be obtained after the procedure. Complications of thoracentesis include infection, pneumothorax, and bleeding. Thoracentesis on the right may be complicated by puncture or laceration of the capsule of the liver and, on the left, by puncture or laceration of the capsule of the spleen. Specimens obtained should always be cultured, examined microscopically for evidence of bacterial infection, and evaluated for total protein and total differential cell counts. Lactic acid dehydrogenase, glucose, cholesterol, triglyceride (chylous), and amylase determinations may also be useful. If malignancy is suspected, cytologic examination is imperative.

Transudates result from mechanical factors influencing the rate of formation or reabsorption of pleural fluid and generally require no further diagnostic evaluation. *Exudates* result from inflammation or other disease of the pleural surface and underlying lung and require a more complete diagnostic evaluation. In general, transudates have a total protein of less than 3?g/dL or a ratio of pleural protein to serum protein less than 0.5, a total leukocyte count of fewer than 2,000/mm^3 with a predominance of mononuclear cells, and low lactate dehydrogenase levels. Exudates have high protein levels and a predominance of polymorphonuclear cells (although malignant or tuberculous effusions may have a higher percentage of mononuclear cells). Complicated exudates often require continuous chest tube drainage and have a pH less than 7.20. Tuberculous effusions may have low glucose and high cholesterol content.

LUNG TAP.

Using a technique similar to that used for thoracentesis, a percutaneous lung tap is the most direct method of obtaining bacteriologic specimens from the pulmonary parenchyma and is the only technique other than open lung biopsy not associated with at least some risk of contamination by oral flora. After local anesthesia, a needle attached to a syringe containing nonbacteriostatic sterile saline is inserted using aseptic technique through the inferior aspect of an intercostal space in the area of interest. The needle is rapidly advanced into the lung; the saline is injected and reaspirated, and the needle is withdrawn. These actions are performed as quickly as possible. This procedure usually yields a few drops of fluid from the lung, which should be cultured and examined microscopically.

Major indications for a lung tap are roentgenographic infiltrates of undetermined cause, especially those unresponsive to therapy in immunosuppressed patients who are susceptible to unusual organisms. Complications are the same as for thoracentesis, but the incidence of pneumothorax is higher and somewhat dependent on the nature of the underlying disease process. In patients with poor pulmonary compliance, such as children with *Pneumocystis* pneumonia, the rate may approach 30%, with 5% requiring chest tubes. Bronchopulmonary lavage has replaced lung taps for most purposes.

Lung Biopsy.

Lung biopsy may be the only way to establish a diagnosis, especially in protracted, noninfectious disease. In infants and small children, thoracoscopic or open surgical biopsies are the procedures of choice, and in expert hands there is low morbidity. Biopsy through the 3.5-mm diameter pediatric bronchoscopes limits the sample size and diagnostic abilities. As well as ensuring that an adequate specimen is obtained, the surgeon can inspect the lung surface and choose the site of biopsy. In older children, transbronchial biopsies can be performed using flexible forceps through a bronchoscope, an endotracheal tube, a rigid bronchoscope, or an endotracheal tube, usually with fluoroscopic guidance. This technique is most appropriately used when the disease is diffuse, such as *Pneumocystis* pneumonia, or after rejection of a transplanted lung. The diagnostic limitations related to the small size of the biopsy specimens can be mitigated by the ability to obtain several samples. The risk of pneumothorax related to bronchoscopy is increased when transbronchial biopsies are part of the procedure; however, the ability to obtain biopsy specimens in a procedure performed with topical anesthesia and conscious sedation offers advantages to the select population for whom this procedure offers a reasonable diagnostic yield.

Sweat Testing.

Chapter 360 - Sudden Infant Death Syndrome

1380

Carl E. Hunt
Fern R. Hauck

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant that is unexpected by history and unexplained by a thorough postmortem examination, which includes a complete autopsy, investigation of the scene of death, and review of the medical history. An autopsy is essential to identify natural causes of death such as congenital anomalies or infection and to diagnosis traumatic child abuse (Table 360–1). The autopsy cannot distinguish between SIDS and intentional suffocation, but the scene investigation and medical history may be of some help if inconsistencies are evident.

Epidemiology.

SIDS is the third leading cause of infant mortality in the United States and the most common cause of postneonatal infant mortality (1 mo–1 yr of age). The annual rate of SIDS in the United States was stable at 1.3–1.4/1,000 live births (about 7,000 infants/yr) before 1992, the year in which the American Academy of Pediatrics first recommended that infants sleep nonprone as a way to reduce the risk of SIDS. Since then, particularly after initiation of the national Back to Sleep campaign in 1994, the rate of SIDS progressively declined to 0.70/1,000 in 1999 (2,648 infants). The decline in the number of SIDS deaths in the United States and other countries around the world has been attributed to the decreasing use of the prone position for sleep. Several other countries have decreased prone sleeping prevalence to 2% or less, but in the United States 12–35% of infants (depending on other characteristics) are still being placed prone for sleeping.

Pathology.

There is no autopsy finding pathognomonic of SIDS and no finding required for the diagnosis. There are, however, some common observations. Petechial hemorrhages are found in more than 90% of cases and may be more extensive than in other causes of infant mortality. Pulmonary edema is often present and may be substantial.

There are tissue markers indicative of pre-existing, chronic low-grade asphyxia in nearly two thirds of SIDS subjects, including persistence of adrenal brown fat, hepatic erythropoiesis, brainstem gliosis, and other structural abnormalities. In addition to astrogliosis, the brainstem abnormalities include hypomyelination and persistent dendritic spines, especially in the magnocellular nucleus of the reticular formation and dorsal and solitary nuclei of the vagal nerve. Significant increases in the number of reactive astrocytes in the medulla have also been observed; these increases are not confined to areas related to respiratory neuroregulation. Substance P, a neuropeptide

TABLE 360-1 -- Differential Diagnosis of Sudden Unexpected Death in Infancy

Cause of Death	Primary Diagnostic Criteria	Confounding Factor(s)	Frequency Distribution
Explained at Autopsy			
Natural			18–20%*
Infections	History, autopsy, and cultures	If minimal findings: SIDS	35–46%†
Congenital anomaly	History and autopsy	If minimal findings: SIDS or intentional suffocation	14–24%†
Unintentional injury	History, scene investigation, autopsy	Traumatic child abuse	15%*
Traumatic child abuse	Autopsy and scene investigation	Unintentional injury	13–24%*
Other natural causes	History and autopsy	If minimal findings: SIDS or intentional suffocation	12–17%*
Unexplained at Autopsy			
Sudden infant death syndrome (SIDS)	History, scene investigation, absence of explainable cause at autopsy	Intentional suffocation	80–82%
Intentional suffocation (filicide)	Perpetrator confession, absence of explainable cause at autopsy	SIDS	Unknown

transmitter found in selected sensory neurons of the central nervous system, is present in increased amounts in the pons of SIDS victims. Quantitative three-dimensional anatomic studies indicate that a small subset of SIDS victims have hypoplasia of the arcuate nucleus; this region is a site of cardiorespiratory control in the ventral medulla and is integrated with other regions that regulate arousal, autonomic, and chemosensory function. Neurotransmitter studies have also identified receptor abnormalities in the arcuate nucleus in some SIDS victims, including significant decreases in binding to kainate receptors, muscarinic cholinergic receptors, and serotonergic receptors. There is a positive correlation between decreased density of muscarinic cholinergic and kainate receptors. The neurotransmitter deficits in the arcuate nucleus thus involve more than one receptor type relevant to autonomic control overall and especially to cardiorespiratory control, including arousal responsiveness. Finally, tyrosine hydroxylase immunoreactivity in two brainstem areas, vagal nuclei and reticularis superficialis ventrolateralis, suggests that epinephrine and norepinephrine neurons are altered in SIDS victims.

Postmortem observations are also consistent with pre-existing, low-grade, chronic asphyxia. SIDS infants as a group have both prenatal and postnatal growth retardation and elevated blood cortisol levels. Elevated levels of hypoxanthine in vitreous humor have been reported, suggesting a relatively long period of tissue hypoxia preceding the death. Because adenosine, a precursor of hypoxanthine, is a respiratory inhibitor, these observations suggest a potentially important interaction between asphyxia and hypoventilation; in response to asphyxia from any cause, the secondary acceleration of adenosine monophosphate catabolism and adenosine accumulation will create a vicious cycle, leading to progressive hypoventilation.

Polymorphisms in the serotonin transporter gene have been studied in genomic DNA from Japanese SIDS victims. The L and XL alleles were found more frequently in SIDS than in healthy control infants. These findings suggest higher reuptake activity in SIDS victims than in controls and hence lower serotonin concentrations in the extracellular space. Because serotonin exerts potent excitatory effects on respiratory control in the brain, these findings are consistent with impaired cardiorespiratory control in affected infants.

Postmortem molecular analyses in SIDS cases have identified mutations on the cardiac sodium-channel gene *(SCN5A);* some SIDS cases, therefore, might be related to a lethal arrhythmia

---

associated with prolonged QT interval caused by an identifiable sodium channel genetic abnormality. Clinical studies have also implicated prolongation of the QT interval as a cause of SIDS (Box 360–1). The prevalence of prolonged QT interval (>440?msec) among all SIDS deaths has not been determined, but a prolonged QT interval during the first week of life increases the risk of SIDS.

Environmental Risk Factors.

Declines of 50% or more in rates of SIDS around the world after national education campaigns directed at the risk factors associated with SIDS have occurred during the past decade. These declines in SIDS rates can be attributed largely to reductions in placing infants prone for sleep and increases in placing them supine. A number of other risk factors also have significant associations with SIDS (Box 360–2).

NONMODIFIABLE RISK FACTORS.

Although SIDS affects infants from all social strata, lower socioeconomic status has been consistently associated with higher risk. In the United States, African-American and Native American infants are two to three times more likely than white infants to die of SIDS, whereas Asian, Pacific Islander, and Hispanic infants have the lowest incidence of SIDS. Some of this disparity may be related to the higher concentration of poverty and other adverse environmental factors found within African-American and Native American communities.

Infants are at highest risk of SIDS at 2–4 mo of age, with most deaths having occurred by 6 mo. However, this characteristic age has decreased in some countries as SIDS incidence has declined, with deaths occurring at earlier ages and a flattening of the peak incidence. Similarly, the commonly found winter seasonal predominance of SIDS has declined or disappeared in some countries as prone prevalence has decreased, supporting prior findings of an interaction between sleep position and factors more common in colder months (e.g., overheating and infection). Male infants have been found to be 30–50% more likely to be affected than females.

MODIFIABLE RISK FACTORS

Pregnancy-Related Factors. An increased SIDS risk is associated with numerous obstetric factors, suggesting that the in utero environment of future SIDS victims is suboptimal. SIDS infants are more commonly of higher birth order, independent of maternal age, and of gestations following shorter interpregnancy intervals. Mothers of SIDS infants generally receive less prenatal care and initiate care later in pregnancy. Additionally, low birth weight, preterm birth, and slower intrauterine and postnatal growth rates are risk factors.

Maternal smoking during pregnancy significantly increases the risk for SIDS. The incidence of SIDS was about three times greater among infants of smokers in studies conducted before SIDS risk reduction campaigns and five times higher after implementation of campaigns, implying that smoking has become an

Box 360-1. Genetic or Biologic Risk Factors That Have Been Associated with SIDS

- Deficient regulation of brainstem autonomic control:
  - Arousal/gasping
  - Ventilatory responsiveness
  - Respiratory pattern
  - Heart rate
  - Temperature
  - Vagal tone
  - Blood pressure
  - Sleep/circadian rhythm
- Family history of SIDS in a sibling
- Idiopathic apparent life-threatening event
- Prematurity
- Metabolic (e.g., fatty acid defects)
- Abnormal inflammatory/immune response to infection
- Prolonged QT syndrome

Box 360-2. Environmental Factors Associated with Increased Risk for SIDS

MATERNAL AND ANTENATAL RISK FACTORS

- Smoking
- Drug exposure (e.g., cocaine, heroin)
- Nutritional deficiency
- Inadequate prenatal care
- Low socioeconomic status
- Decreased age, education
- Single marital status
- Increased parity
- Shorter interpregnancy interval
- Intrauterine hypoxia
- Fetal growth retardation

INFANT RISK FACTORS:

- Age (peak 2–4 mo, but may be decreasing)
- Male gender
- Race/ethnicity (e.g., African-American and Native American)
- Growth failure
- No pacifier (dummy)
- Prematurity
- Prone (and side) sleep position
- Recent (febrile) illness

Prematurity

Prone (and side) sleep position

Recent (febrile) illness

Smoking exposure (prenatal and postnatal)

Soft sleeping surface, soft bedding

Thermal stress/overheating

Colder season, no central heating

increasingly important risk factor as prone prevalence rates have declined. Most studies have shown that the risk of death is progressively greater as daily cigarette use increases, but the accuracy of self-reported cigarette use data is uncertain. The effects of smoking by the father and other household members are more difficult to interpret because they are highly correlated with maternal smoking. There appears to be a small independent effect of paternal smoking, but data on other household members have been inconsistent.

The evidence linking prenatal illegal drug use and SIDS is conflicting. Overall, the studies do link maternal prenatal drug use with an increased risk of SIDS. The majority of published studies have not found an association between maternal alcohol use prenatally or postnatally and SIDS. In one study of Northern Plains Indians, however, drinking and, particularly, binge drinking were more common among mothers of SIDS infants.

Infant Sleep Environment. Sleeping prone has consistently been shown to increase the risk of SIDS. As rates of prone positioning have decreased in the general population, the odds ratios for SIDS in infants still sleeping prone have increased. The highest risk of SIDS may occur in infants who are usually placed nonprone but were placed prone for last sleep (“unaccustomed prone”) or were found prone (“secondary prone”). The “unaccustomed prone” position is more likely to occur in daycare or other settings outside the home and highlights the need for all persons caring for infants to be educated about appropriate sleep positioning.

The initial SIDS risk reduction campaign recommendations considered side sleeping to be nearly equivalent to the supine position in reducing the risk of SIDS. Subsequent studies, however, have indicated that, although much safer than the prone position, side-sleeping infants are twice as likely to die of SIDS compared with infants sleeping supine. This increased risk may relate to the relative instability of the position, with some infants placed in the side rolling to the prone position. Thus, the current recommendations call for supine position for sleeping for all infants except the few infants with a specific medical contraindication such as micrognathia, macroglossia, or perhaps severe gastroesophageal reflux.

Many parents and health care providers were initially concerned that supine sleeping would be associated with an increase in adverse consequences, such as trouble sleeping,

vomiting, or aspiration, even though some evidence suggests that the risk of regurgitation and choking are highest for prone-sleeping infants. Infants sleeping on their backs do not have more episodes of cyanosis or apnea, and reports of apparent life-threatening events decreased in Scandinavia after increased use of the supine position. Among infants in the United States who maintained the same sleep position at 1, 3, and 6 months of age, no clinical symptoms or reasons for outpatient visits (including fever, cough, wheezing, trouble breathing or sleeping, vomiting, diarrhea, or respiratory illness) were significantly more common in infants sleeping on their side or supine compared with infants sleeping prone. Three symptoms were actually less common in infants sleeping supine or on their side: fever at 1 mo, stuffy nose at 6 mo, and trouble sleeping at 6 mo. Outpatient visits for ear infection were less common at 3 and 6 mo for infants sleeping supine and less common at 3 mo for infants sleeping on their side. These results provide reassurance for parents and practitioners and will hopefully lead to progressively greater acceptance of supine as the safest and most appropriate sleep position for infants.

Soft sleep surfaces or bedding, such as comforters, pillows, sheepskins, polystyrene bean pillows, and older or softer mattresses are associated with increased risk of SIDS. Head and face covering by loose bedding, particularly heavy comforters, is also associated with increased risk. Overheating has been associated with increased risk for SIDS based on indicators such as higher room temperature, high body temperature, sweating, and excessive clothing or bedding. Some studies have identified an interaction between overheating and prone sleeping, with overheating increasing the risk of SIDS only when infants were sleeping prone.

A few studies have implicated bed sharing as a risk factor for SIDS. In seven early case-controlled studies, five showed an increased risk of SIDS, one showed a trend toward increased risk, and one small study showed a trend toward lower risk. Case-controlled studies in England and New Zealand found increased risk associated with bed sharing only among smoking mothers. Bed sharing has been found to be particularly hazardous when other children are in the same bed, when parents are co-sleeping on a couch or other soft or confining sleeping surface, and for infants younger than 4 mo of age. Some authors have hypothesized potentially protective effects among infants who are bed sharing and breast-feeding based on observational sleep laboratory studies, including improved maternal inspections, more infant arousals, and less deep sleep. However, no epidemiologic studies have reported a protective effect from bed sharing, and bed sharing hence should not be encouraged as a method to reduce the incidence of SIDS.

Infant Feeding Care Practices and Exposures. The association between breast-feeding and SIDS is inconclusive. A number of studies have demonstrated a protective effect of breast-feeding that was not present after adjusting for potentially confounding factors. This suggests that it is a marker for lifestyle or socioeconomic status rather than having an independent effect. Although the benefits of breast-feeding are many, data are inadequate to recommend it as a strategy to reduce SIDS.

Pacifier (dummy) use has been found to significantly lower the risk of SIDS in every reported study, both when used routinely and for last/reference sleep. It is not known

if this is a direct effect of the pacifier itself or from associated infant or parental behaviors. Concerns have been expressed about recommending pacifiers as a means of reducing the risk of SIDS for fear of creating adverse consequences, particularly interference with breast-feeding. However, no association between pacifiers and breast-feeding duration has been found. An increased incidence of otitis media and of respiratory and gastrointestinal illness has been reported for pacifier users compared with nonusers. The Netherlands (for bottle-fed babies) and Germany have recommended pacifier use as a way to potentially reduce the risk of SIDS.

Upper respiratory tract infections have not been found to be an independent risk factor. These and other minor infections, however, may play a role in the pathogenesis of SIDS. Risk for SIDS, for example, was found to be increased after illness only among prone sleepers or among those who were heavily wrapped.

No association between immunizations and SIDS has been found. However, SIDS infants are less likely to be immunized than control infants and no temporal relationship between vaccine administration and death has been identified. Parents should be reassured that immunizations do not present a risk for SIDS.

There is a major association between intrauterine exposure to cigarette smoking and risk for SIDS. It is very difficult to assess the independent effect of infant exposure to environmental tobacco smoke (ETS) because parental smoking behaviors during and after pregnancy are highly correlated. Only one study examined the effect of maternal smoking after the birth of the infant in the absence of maternal smoking during pregnancy; an increased risk of SIDS was found for infants exposed to maternal ETS. In one U.S. study, an independent effect of postnatal ETS was found by controlling for maternal prenatal smoking; additionally, a dose response was found for the number of household smokers, number of people smoking in the same room as the infant, and the number of cigarettes smoked, although confidence intervals were large in some categories owing to small sample size. A British study also found a dose response of ETS to the number of household smokers, cigarettes smoked, and hours the infant was exposed. The data suggest that keeping the infant free of ETS may potentially further reduce an infant's risk of SIDS.

Parental smoking is the most important risk factor for SIDS on a population basis. The population attributable risk (i.e., proportion of cases that would not have occurred had the risk factor been eliminated in the population) is 48% assuming a 25% prevalence of maternal smoking. Motivating families to quit smoking (particularly during pregnancy) is much more difficult than asking them to change behaviors related to infant sleeping position or other factors associated with a safe sleep environment, however, making this endeavor a major challenge for the professional health community.

Disparities in SIDS rates among some ethnic-racial groups have increased in recent years. This may be due to group differences in adopting nonprone sleeping or other risk reduction behaviors. For example, 32% of African-American infants but only 17% of white infants were usually placed prone for sleep as reported by parents responding to a 1998 national survey of infant care practices. Greater efforts are needed to address this growing disparity and to ensure that SIDS risk reduction education reaches all parents. Further, the messages must reach all care providers, including grandparents, other relatives, and personnel at daycare centers.

Genetic Risk Factors.

Data are accumulating that link specific genotypes to impaired brainstem regulation of breathing or other autonomic control as a risk factor for SIDS (see Box 360–1 and Table 360–2). Neural control of breathing and sleep are closely integrated, and abnormalities in regulation of sleep and circadian rhythmicity can hence impair cardiorespiratory integration and arousal responsiveness from sleep. Homologous counterparts of essential circadian clock genes isolated in Drosophilae have been identified in mammals. Because the sleep-wake cycle is under control of the circadian clock, these circadian master genes, as well other sleep-related genes, likely influence sleep regulation.

Furthermore, targeted gene inactivation studies in animals have identified several genes involved with prenatal brainstem

TABLE 360-2 -- **Summary of Data Providing Direct or Indirect Evidence for Genetic Susceptibility to SIDS**

Category of Data	Primary Limitations(s)
Infant Mortality Studies	
Increased risk for recurrent SIDS in siblings	Unknown number of intentional suffocations
	May include some explained causes
	Scant data about environmental risk factors
Increased risk for recurrent non-SIDS causes of infant mortality in siblings	Unable to quantify contributions from common environmental risk factors
Neuropathology Studies in SIDS Victims and Animals	Causal relationship of these abnormalities to pathophysiology of SIDS not established
Physiologic Studies	
Subsequent siblings of SIDS	Unknown role of intentional suffocation in index cases and in surviving siblings
	Causal relationship of these abnormalities to pathophysiology of SIDS not established

Parents of SIDS	Small studies with variable results
	Causal relationship of these abnormalities to pathophysiology of SIDS not established
Genetic Studies of Sleep Regulation	Unknown if SIDS is exclusively a sleep-related disorder
	Causal importance to SIDS of sleep state and arousability from sleep not fully established
Family Studies	
Obstructive sleep apnea syndrome (OSAS) or sleep-disordered breathing (SDB)	Unclear relationship of apparent life-threatening event to SIDS
	Genetic risk factors for OSAS (SDB) not fully delineated
	Limited information about the SIDS cases in these kindreds

development of respiratory control, including arousal responsiveness. During embryogenesis, for example, the survival of specific cellular populations composing the respiratory neuronal network is regulated by neurotrophins, a multigene family of growth factors and receptors. Brain-derived neurotrophic factor is required for development of normal breathing behavior in mice, and newborn mice lacking functional brain-derived neurotrophic factor exhibit ventilatory depression associated with apparent loss of peripheral chemoafferent input. Ventilation is depressed, and hypoxic ventilatory drive is deficient or absent. *Krox-20*, a homeobox gene important for hindbrain morphogenesis, also appears to be required for normal development of the respiratory central pattern generator. *Krox-20* null mutants exhibit an abnormally slow respiratory rhythm and increased incidence of respiratory pauses, and this respiratory depression can be further modulated by endogenous enkephalins. Inactivation of *Krox-20* may result in absence of a rhythm-promoting reticular neuron group localized in the caudal pons and could thus be a cause of life-threatening apnea.

Brainstem muscarinic cholinergic pathways are important in ventilatory responsiveness to CO_2 . The muscarinic system develops from the neural crest, and the *ret* proto-oncogene is important for this development. *Ret* knockout mice have a depressed ventilatory response to hypercarbia, implicating absence of the *ret* gene as a cause of impaired hypercarbic responsiveness. Diminished ventilatory responsiveness to hypercarbia has also been demonstrated in male newborn mice heterozygous for *Mash-1*. There is a molecular link between *ret* and *Mash-1*, and the latter is expressed in embryonic neurons before the former is expressed in vagal neural crest derivatives and in brainstem locus coeruleus neurons, an area involved with arousal responsiveness. *Mash-1* thus appears to be involved in respiratory control development through mechanisms linked to the X chromosome. Abnormality of this gene identifies one possible genetic basis for the increased frequency of SIDS in males and for the impaired arousal responsiveness thought to be critically important in the pathophysiology of SIDS.

Gene-Environment Interaction.

Based on the abundant evidence for environmental risk factors for SIDS (see Box 360–2) and the emerging evidence for genetic risk factors, the mechanism for SIDS in individual infants may best be understood as a consequence of one or more environmental risk factors interacting with one or more genetic risk factors. There appears to be an interaction between prone/side sleep position and impaired cardiorespiratory control, for example, especially impaired ventilatory and arousal responsiveness. Face-down or nearly face-down sleeping does occasionally occur in healthy prone-sleeping infants and can result in episodes of airway obstruction and asphyxia in healthy full-term infants, especially if they are sleeping on a very soft surface. Although healthy infants will arouse before the face-down or face-nearly-down position becomes life threatening, infants with insufficient arousal responsiveness to asphyxia would be at risk for fatal asphyxia. In addition, prone sleeping may cause a clinically significant degree of thermal stress, which could further compromise infants with deficient cardiorespiratory control. There thus may be links between modifiable risk factors such as soft bedding, prone sleep position, and thermal stress and links between genetic risk factors such as cardiorespiratory control deficits (ventilatory and arousal abnormalities) and temperature/metabolic regulation deficits.

The increased risk for SIDS associated with fetal and postnatal exposure to cigarette smoke also appears at least in part to depend on genetic factors affecting brainstem autonomic control. Animal studies demonstrate impaired ventilatory and arousal responsiveness to hypoxia associated with fetal exposure and impaired autoresuscitation after apnea in association with postnatal nicotine exposure. In addition, fetal rat exposure to maternal smoking reduces protein kinase C within the dorsocaudal brainstem, which would impair ventilatory and arousal responsiveness to hypoxia.

INFANT GROUPS AT INCREASED RISK FOR SIDS

Unexplained Apparent Life-Threatening Events.

Infants with an unexplained apparent life-threatening event (ALTE) are at increased risk for SIDS. A history of an unexplained ALTE has been reported in about 5% of SIDS victims, and the risk of SIDS may be higher with two or more unexplained ALTEs. Compared with healthy control infants, the risk for SIDS after an ALTE may be as much as three to five times greater.

Subsequent Siblings of a SIDS Victim.

The extent to which risk for SIDS may be increased in subsequent siblings is controversial, owing in part to uncertainty about the frequency with which intentional suffocation is misclassified as SIDS. Clarification of the role of intentional suffocation has been impaired by the lack of objective criteria for diagnosis. Based on a few families with multiple sudden, unexpected infant/child fatalities and later parental confession or conviction, however, some health

professionals have stated that only homicide runs in families and all second cases of SIDS in a family should be investigated for possible homicide. However, there are also substantial data in support of genetic as well as environmental factors leading to increased risk of death from natural causes in siblings in some families. The next-born siblings of first-born infants dying of any noninfectious cause are at significantly increased risk for infant death from the same cause, including SIDS (see Table 360–2). The relative risk for recurrence of each cause of infant death is similar for SIDS and for each of the explainable natural causes. Compared with first-born infants in families, subsequent siblings of a previous SIDS victim appear to be approximately five times more likely to die of SIDS. Although many of the studies have limitations (see Table 360–2), when considered in the aggregate, the evidence is strong that recurrent infant mortality in families can be due to a combination of genetic and environment risk factors, in addition to intentional suffocation.

Prematurity.

Many studies have identified an inverse relationship between risk for SIDS and birthweight/gestational age. The environmental risk factors associated with SIDS in preterm infants are not substantially different than those observed in full-term infants, including prone and side sleeping. However, the postnatal age of preterm infants dying of SIDS is 5–7 wk older than full-term infants, and the postconceptional age is 4–6 wk younger than full-term infants. Compared with infants with birth weight greater than 2500?g, infants with birth weights of 1000–1499?g and 1500–2499?g are approximately four and three times more likely to die of SIDS, respectively.

Physiologic Studies.

Physiologic studies have been performed in infants at increased risk for SIDS, a few of whom later died of SIDS. These studies are most consistent with a brainstem abnormality related to neuroregulation of cardiorespiratory control or other brainstem autonomic functions (see Box 360–1).

RESPIRATORY PATTERN AND CHEMORECEPTOR SENSITIVITY.

The respiratory pattern abnormalities have included prolonged apnea, excess brief apneas, periodic breathing, and decreased breath-to-breath respiratory rate variability at slow respiratory rates. Some infants at increased risk for SIDS have diminished ventilatory responsiveness to hypercarbia and/or to hypoxia, but there is a high degree of individual overlap between normal and at-risk infants.

AROUSAL RESPONSES.

Absent arousal responsiveness renders infants incapable of responding effectively to sleep-related asphyxia from any cause. Infants at increased risk for SIDS who have diminished ventilatory responsiveness to hypercarbia and/or hypoxia generally have a concomitant abnormality in hypercarbic and/or hypoxic arousal responsiveness. A deficit in arousal responsiveness may be a necessary prerequisite for SIDS to occur but may be insufficient to cause SIDS in the absence of other genetic or environmental risk factors. Victims of SIDS may also have deficient autoresuscitation (gasping) as a component of the asphyxic arousal response deficit; this would be the final and most devastating physiologic failure

In full-term infants with ALTE, the occurrence and severity of recurrent symptoms correlate with arousal responsiveness. Most full-term infants younger than 9 wk of age arouse in response to mild hypoxia, but only 10–15% of normal infants greater than 9 wk of age arouse. This suggests that as full-term infants mature, their ability to arouse to mild-moderate hypoxic stimuli diminishes as they reach the age range of greatest risk for SIDS. However, there is significant overlap in individual values between healthy term controls and infants in groups at increased risk for SIDS.

TEMPERATURE REGULATION.

Sweating during sleep has been observed in some infants who have had an idiopathic ALTE or have died of SIDS. Although overheating may be the cause of this sweating, it may also be caused by alveolar hypoventilation and secondary asphyxia or by autonomic dysfunction as part of a more generalized deficiency in brainstem function.

CARDIAC CONTROL.

The ability to shorten QT interval as heart rate increases is impaired in some SIDS infants, and some have prolongation of the QT interval (>440?msec), suggesting that such infants may be predisposed to ventricular arrhythmia. The prevalence of prolonged QT interval among all SIDS deaths has not been determined, but a prolonged QT interval during the first week of life does increase the risk of SIDS. Infants later dying of SIDS compared with normal infants also have higher heart rates in all sleep-waking states, diminished heart rate variability during wakefulness, and lower heart rate variation at a given respiratory frequency across all sleep-waking cycles. Thus, future SIDS victims differ from normal in the extent to which cardiac and respiratory activities are coupled.

Part of the decreased heart rate variability and increased heart rate observed in infants who later die of SIDS may be related to decreased vagal tone. This could be caused by vagal neuropathy, brainstem damage in areas responsible for parasympathetic cardiac control, or other factors. Furthermore, because the greatest reduction in all types of heart rate variability occurs while awake, these reductions may be related to the reduced motility retrospectively reported in SIDS victims and also observed in some infants at increased risk for SIDS. Comparing heart rate power spectra before and after obstructive apneas in infants, future SIDS victims did not have the decreases in low-frequency to high-frequency power ratios observed in control infants. Some future SIDS victims thus have different autonomic responsiveness to obstructive apneas, perhaps indicating a dysautonomia that could be associated with higher vulnerability to external or endogenous stress factors and result in reduced electrical stability of the heart and hence ventricular fibrillation.

TERMINAL RECORDINGS IN SIDS VICTIMS.

Home cardiorespiratory monitors with memory capability have recorded some

terminal events in SIDS victims. All of these terminal recordings utilized transthoracic impedance for breath detection, which cannot detect obstructed breaths, and most did not include pulse oximetry recordings of O_2 saturation. Therefore, one cannot reach any conclusions from these recordings as to whether the terminal event was initiated by apnea, bradycardia, desaturation, or a combination of these findings. In most instances, there has been sudden and rapid progression of severe bradycardia either preceding or at the onset of central apnea and hence too soon to be explained by the prolonged central apnea. These recordings are consistent with an abnormality in autonomic control of heart rate variability or with hypoxemia (not recorded) secondary to obstructive apnea (not recorded) as the precipitating mechanism for the severe bradycardia and fatal outcome.

CLINICAL STRATEGIES

Monitoring.

SIDS cannot be prevented in individual infants because it is not possible currently to prospectively identify future SIDS victims or effectively intervene. Studies of respiratory pattern and/or cardiac abnormalities do not have sufficient sensitivity and specificity to be clinically useful as a screening test. Home electronic surveillance does not reduce the risk of SIDS. It might have a preventive role in the future, however, if obstructed breaths, central apnea, bradycardia, or oxygen desaturation occurring as part of the terminal event could be reliably detected sufficiently early so as to be amenable to intervention. Although prolonged QT interval in an infant may be treated if diagnosed, neither the role of routine postnatal electrocardiographic (ECG) screening nor the safety of treatment has been established. Parental ECG screening is not likely to be helpful because spontaneous mutations are common.

Reducing the Risk of SIDS.

This goal is achievable, as evidenced by the dramatic decreases in SIDS rates in association with reduction in nonsupine sleeping. The American Academy of Pediatrics guidelines to reduce the risk of SIDS in individual infants are appropriate for most infants, but physicians and other health care providers may on occasion need to consider alternative approaches. The major components are as follows:

1. Full-term and premature infants should be placed for sleep in the supine position. There are no adverse health outcomes from supine sleeping. Side sleeping is not recommended.
2. A crib meeting federal safety standards is a desirable sleeping environment for infants. Safety standards have not been established for bassinets and cradles. Sleep surfaces designed for adults may pose hazards to infants, such as entrapment.
3. Infants should not be put to sleep on waterbeds, sofas, soft mattresses, or other soft surfaces.
4. Soft materials in the infant's sleep environment should be avoided, either over, under, or near the infant. These include pillows, comforters, quilts, sheepskins, and stuffed toys. Because loose bedding may be hazardous, blankets, if used, should be tucked in around the crib mattress. Sleeping clothing (such as a sleep sack) may be used in place of blankets.
5. Bed sharing or co-sleeping may be hazardous under some conditions. Adults (other than parents) and children or other siblings should not share a bed with an infant. The parents should not share a bed with their infant if they smoke or use substances such as drugs or alcohol that impair parental arousal. The other risk reduction recommendations should be followed, such as placing the infant supine and avoiding soft bedding. As an alternative to bed sharing, parents may wish to place the crib near their bed.
6. Avoid overheating and overbundling. The infant should be lightly clothed for sleep and the thermostat set at a comfortable temperature.
7. Infants should have some time in the prone position while awake and observed. Alternating the placement of the infant's head as well as his or her orientation in the crib can also minimize the risk of head flattening from supine sleeping.
8. Devices advertised to maintain sleep position or reduce the risk of rebreathing are not recommended.
9. Home respiratory, cardiac, and O_2 saturation monitoring may be of value for selected infants who have extreme instability, but there is no evidence that its use decreases the incidence of SIDS and it is, therefore, not recommended for this purpose.
10. The national Back to Sleep campaign should continue and be expanded to emphasize the multiple characteristics of a safe sleeping environment and to focus on the groups who continue to have higher prevalence rates for placing infants prone for sleeping. Educational strategies must be tailored to different racial-ethnic groups to ensure acceptance within diverse cultural contexts. Other risk reduction messages also should be included.

Section 2 - *Upper Respiratory Tract*

Children and adults preferentially breathe through their nose unless nasal obstruction interferes. However, most newborn infants are obligate nasal breathers, and significant nasal obstruction presenting at birth, such as choanal atresia, may be a life-threatening situation for the infant unless an alternative to the nasal airway is established.

Physiology. In addition to olfaction, the nose provides initial warming and humidification of inspired air. In the anterior nasal cavity, turbulent airflow and coarse hairs enhance the deposition of large particulate matter; the remaining nasal airways filter out particles as small as 6?µm in diameter. In the turbinate region, the airflow becomes laminar and the air stream is narrowed and directed superiorly, enhancing particle deposition, warming, and humidification. Nasal passages contribute as much as 50% of the total resistance of normal breathing. *Nasal flaring*, a sign of respiratory distress, reduces the resistance to inspiratory airflow through the nose and may improve ventilation.

The nasal mucosa is more vascular, especially in the turbinate region, than in the lower airways; however, the surface epithelium is similar, with ciliated cells, goblet cells, submucosal glands, and a covering blanket of mucus. In addition to mucous glycoproteins, which provide viscoelastic properties, the nasal secretions contain lysozyme and secretory IgA, both of which have antimicrobial activity, and IgG, IgE, albumin, histamine, bacteria, lactoferrin, and cellular debris. Aided by the ciliated cells, mucus flows toward the nasopharynx, where the air stream widens, the epithelium becomes squamous, and secretions are wiped away by swallowing; replacement of the mucous layers occurs about every 10–20 min. Estimates of daily mucus production vary from 0.1–0.3?mg/kg/24?hr, with most of the mucus being produced by the submucosal glands.

Anatomy. The paranasal sinuses develop in the facial bones as air cells lined with ciliated, mucus-secreting epithelium. The frontal, maxillary, and anterior ethmoid sinuses drain into the middle meatus, whereas the posterior ethmoid cells and sphenoidal sinus drain into the superior meatus of the nose. Development of the sinuses begins at 3–5 mo of gestation but occurs mostly after birth, with the maxillary and ethmoidal sinuses being the earliest to form (see Chapter 365). Growth of the sinuses continues through adolescence, with the frontal and sphenoidal sinuses often being somewhat asymmetric; up to 5% of the population has no significant

frontal sinus development. Hypoplasia of the maxillary sinuses, or the presence of septa within the maxillary sinuses, is seen occasionally.

The adenoids on the posterior nasopharyngeal wall and the tonsils at the base of the tongue are directly in line with the mucociliary flow and the air stream, enhancing the protective function of this lymphoid tissue. The eustachian tubes, also lined with mucus-secreting, ciliated epithelium, enter the lateral walls of the nasopharynx and connect the nasopharynx to the middle ear.

Acquired anatomic abnormalities suggestive of sinusitis seen on plain sinus radiographs include mucosal thickening greater than 4 mm, air-fluid levels, or opacification; plain sinus radiographs in children younger than 7 yr of age may be difficult to interpret. High-resolution CT of the paranasal sinuses, the current gold standard for evaluation of disease of the paranasal sinuses, often reveals abnormalities, either congenital or acquired, that are not seen on plain films.

Chapter 361 - Congenital Disorders of the Nose

Joseph Haddad Jr.

Congenital *structural nasal malformations* are uncommon compared with acquired abnormalities. The nasal bones may be congenitally absent so that the bridge of the nose fails to develop, resulting in nasal hypoplasia. Congenital absence of the nose (arhinia), complete or partial duplication, or a single centrally placed nostril may occur in isolation but are usually a part of malformation syndromes. Rarely, supernumerary teeth may be found in the nose, or teeth may grow into it from the maxilla.

On occasion, nasal bones are sufficiently malformed to produce severe narrowing of the nasal passages. Often such narrowing is associated with a high and narrow hard palate. Children with these defects may have significant obstruction to airflow during infections of the upper airways and are more susceptible to the development of chronic or recurrent hypoventilation (see Chapter 369). Rarely, the alae nasi may be sufficiently thin and poorly supported to result in inspiratory obstruction, or there may be congenital nasolacrimal duct obstruction with cystic extension into the nasopharynx causing respiratory distress.

Nasal congestion with obstruction is common during the first year of life and may affect the quality of breathing during sleep; it may be associated with a narrow nasal airway, viral or bacterial infection with congestion, enlarged adenoids, or maternal estrogenic stimuli similar to rhinitis of pregnancy. The internal nasal airway doubles in size during the first 6 mo of life, leading to resolution of symptoms in many infants. Supportive care with a bulb syringe and saline nose drops, topical nasal decongestants, and antibiotics, when indicated, will improve symptoms in affected infants.

A wide variety of nasal and midface abnormalities exist that may be part of more extensive craniofacial anomalies. These children are best treated by a team consisting of experienced pediatric, surgical, dental, and rehabilitation specialists.

Choanal Atresia.

This is the most common congenital anomaly of the nose and has a frequency of approximately 1/7,000 live births. It consists of a unilateral or bilateral bony (90%) or membranous (10%) septum between the nose and the pharynx; most cases are a combination of bony and membranous atresia. Nearly 50% of affected infants have other congenital anomalies, with the anomalies occurring more frequently in bilateral cases. The CHARGE syndrome—*C*oloboma; *H*eart disease; *A*tresia choanae; *R*etarded growth and development or CNS anomalies, or both; *G*enital anomalies or hypogonadism, or both; and *E*ar anomalies or deafness, or both—is one of the more common anomalies associated with choanal atresia.

CLINICAL MANIFESTATIONS.

Newborn infants have a variable ability to breathe through their mouths, so nasal obstruction does not produce the same symptoms in every infant. When unilateral, the infant may be asymptomatic for a prolonged period, often until the first respiratory infection, when the diagnosis may be suggested by nasal discharge or persistent nasal obstruction. Infants with bilateral choanal atresia who have difficulty with mouth breathing make vigorous attempts to inspire, often suck in their lips, and develop cyanosis. Distressed children then cry (which relieves the cyanosis) and become more calm with normal skin color, only to repeat the cycle after closing their mouths. Those who are able to breathe through their mouths at once experience difficulty when sucking and swallowing, becoming cyanotic when they attempt to feed.

DIAGNOSIS.

This is established by the inability to pass a firm catheter through each nostril 3–4?cm into the nasopharynx. The atretic plate may be seen directly with fiberoptic rhinoscopy. The anatomy is best evaluated by using high-resolution CT.

TREATMENT.

Initially, this consists of prompt placement of an oral airway, maintaining the mouth in an open position, or intubation. A standard oral airway may be used (such as that used in anesthesia), or a feeding nipple may be fashioned with large holes at the tip to facilitate air passage. Once an oral airway is established, the infant can be fed by gavage until breathing and eating without the assisted airway is possible. In bilateral cases, intubation or tracheotomy may be indicated. If the child is free of other serious medical problems, operative intervention is considered in the neonate; transnasal

repair is now more common with the introduction of small magnifying endoscopes and smaller surgical instruments and drills. Stents are usually left in place for weeks after the repair to prevent closure or stenosis. Tracheotomy should be considered in cases of bilateral atresia in which the child has other potentially life-threatening problems and in whom early surgical repair of the choanal atresia may not be appropriate or feasible. Operative correction of unilateral obstruction may be deferred for several years. In both unilateral and bilateral cases, re-stenosis necessitating dilation or reoperation, or both, is common. Mitomycin-C has been used to help prevent the development of granulation tissue and stenosis.

Congenital defects of the nasal septum, such as *perforation* or *deviation*, are rare. Perforation can be developmental (very rare) but, more commonly, is acquired after birth secondary to infection, such as syphilis, tuberculosis, or trauma. Continuous positive airway pressure cannulas are a cause of iatrogenic perforation. Trauma from delivery is the most common cause of septal deviation noted at birth. When recognized early, it may be corrected with immediate realignment using blunt probes, cotton applicators, and topical anesthesia. Formal surgical correction, when required, is usually postponed to avoid disturbance of midface growth. Mild septal deviations are common and usually asymptomatic; abnormal formation of the septum is infrequent unless other malformations are present, such as cleft lip or palate.

Pyriform aperture stenosis is a bony abnormality of the anterior nasal aperture. These infants present with severe nasal obstruction at birth or shortly thereafter. Diagnosis is made by CT of the nose; surgical repair by means of an anterior, sublabial approach may be needed if the child cannot feed or breathe without difficulty.

Congenital midline nasal masses include *dermoids, gliomas*, and *encephaloceles* (in descending order of frequency). They present intranasally or extranasally and may have intracranial connections. Nasal dermoids often have a dimple or pit on the nasal dorsum, sometimes with hair being present, and may predispose to intracranial infections if an intracranial connection is present. Recurrent infection of the dermoid itself is common. Gliomas or heterotopic brain tissue are firm, whereas encephaloceles are soft and enlarge with crying or the Valsalva maneuver. Diagnosis is based on physical examination findings and results from imaging studies. CT provides the best bony detail, but MRI allows sagittal views, which may be needed to further define intracranial extension. Surgical excision of these masses is generally required, with the extent and surgical approach based on the type and size of the mass.

Other nasal masses include hemangiomas, congenital nasolacrimal duct obstruction (which may present as an intranasal mass), nasal polyps, and tumors such as rhabdomyosarcoma. Nasal polyps are rarely present at birth, but the others often present at birth or in early infancy (see Chapter 363).

Poor development of the paranasal sinuses and a narrow nasal airway are associated with recurrent or chronic upper airway infection in Down syndrome.

Chapter 362 - Acquired Disorders of the Nose

Joseph Haddad Jr.

362.1 Foreign Body

Food, crayons, small toys, erasers, paper wads, beads, beans, stones, pieces of sponge, and other foreign bodies are frequently introduced into the nose by children. Initial symptoms are local obstruction, sneezing, relatively mild discomfort, and, rarely, pain. Irritation results in mucosal swelling; and, because some foreign bodies are hygroscopic and increase in size as water is absorbed, signs of local obstruction and discomfort may increase with time. Infection usually follows and gives rise to a purulent, malodorous, or bloody discharge. The patient may also present with a generalized body odor known as bromhidrosis. **Disk batteries** are dangerous when placed in the nose; they leach base, which causes pain and local tissue destruction within a matter of hours.

Diagnosis.

Unilateral nasal discharge and obstruction should suggest the presence of a foreign body, which can often be seen on examination with a nasal speculum or otoscope placed in the nose. Purulent secretions must often be removed so that the foreign object can actually be seen; often a headlight, suction, and topical decongestants may be needed. The object is usually situated anteriorly at first, but through unskilled attempts at removal it may be forced deeper into the nose. When of long standing, a foreign body may become embedded in granulation tissue or mucosa and appear as a nasal mass. A lateral skull radiograph assists in diagnosis if the foreign body is metallic or radiopaque.

Treatment.

Removal should be carried out promptly to minimize the danger of aspiration and prevent local tissue necrosis. This can usually be performed with topical anesthesia, using either forceps or nasal suction. If there is marked swelling, bleeding, or tissue overgrowth, general anesthesia may be needed to remove the object. Infection usually clears promptly after the removal of the object, and generally no further therapy is necessary.

Complications.

Tetanus is a rare complication of long-standing nasal foreign bodies in nonimmunized children. Toxic shock syndrome is also rare and most commonly occurs from nasal surgical packing (see Chapter 166.2).

362.2 Epistaxis

Nosebleeds are rare in infancy and common in childhood; their incidence decreases after puberty. Diagnosis and treatment depend on the location and cause of the bleeding.

Anatomy.

The most common site of bleeding is the Kiesselbach plexus, an area in the anterior septum where vessels from both the internal carotid (anterior and posterior ethmoid arteries) and external carotid (sphenopalatine and terminal branches of the internal maxillary arteries) converge. The thin mucosa in this area, as well as the anterior location, make it prone to exposure to dry air and trauma.

Etiology.

Common causes of nosebleeds from the anterior septum include digital trauma, foreign bodies, dry air, and inflammation, including upper respiratory tract infections, sinusitis, and allergic rhinitis. Nasal steroid sprays are commonly used in children, and their chronic use may be associated with bleeding. Young infants with significant gastroesophageal reflux into the nose may occasionally present with epistaxis secondary to mucosal inflammation. In many children, there is frequently a family history of childhood epistaxis. Susceptibility is increased during respiratory infections and in the winter when dry air irritates the nasal mucosa, resulting in formation of fissures and crusting. Severe bleeding may be encountered with congenital vascular abnormalities, such as hereditary hemorrhagic telangiectasia, varicosities, hemangiomas, and, in children with thrombocytopenia, deficiency of clotting factors, hypertension, renal failure, or venous congestion. Nasal polyps or other intranasal growths may be associated with epistaxis. Recurrent, and frequently severe, nosebleeds may be the initial presenting symptom in juvenile nasal angiofibromas, which occur in adolescent males. The incidence of Kiesselbach plexus bleeding seems to decrease during adolescence.

Clinical Manifestations.

Epistaxis usually occurs without warning, with blood flowing slowly but freely from one nostril or occasionally from both. In children with nasal lesions, bleeding may follow physical exercise. When bleeding occurs at night, the blood may be swallowed and may become apparent only when the child vomits or passes blood in the stools. Posterior epistaxis may manifest as anterior nasal bleeding or, if copious, the patient may vomit blood as the initial symptom.

Treatment.

Most nosebleeds stop spontaneously in a few minutes. The nares should be compressed and the child kept as quiet as possible, in an upright position with the head tilted forward to avoid blood trickling back into the throat. Cold compresses applied to the nose may also help. If these measures do not stop the bleeding, local application of a solution of oxymetazoline (Afrin) or Neo-Synephrine (0.25–1%) may be useful. If bleeding persists, an anterior nasal pack may need to be inserted; if bleeding originates in the posterior nasal cavity, combined anterior and posterior packing is necessary. After bleeding has been controlled, and if a bleeding site is identified, its obliteration by cautery with silver nitrate may prevent further difficulties. Because the septal cartilage derives its nutrition from the overlying mucoperichondrium, only one side of the septum should be cauterized at a time to reduce the chance of a septal perforation. During the winter, or in a dry environment, a room humidifier, saline drops, and petrolatum (Vaseline) applied to the septum may help to prevent epistaxis.

In patients with severe or repeated epistaxis, blood transfusions may be necessary. Otolaryngologic evaluation is indicated for these children and for those with bilateral bleeding or with hemorrhage that does not arise from the Kiesselbach plexus. Hematologic evaluation (for coagulopathy and anemia), along with nasal endoscopy and diagnostic imaging, may be needed to make a definitive diagnosis in cases of severe recurrent epistaxis. Replacement of deficient clotting factors may be required for patients who have an underlying hematologic disorder (see Chapter 468). Profuse epistaxis associated with a nasal mass in a boy near puberty may signal a **juvenile nasopharyngeal angiofibroma.** This unusual tumor has been reported in a 2 yr old and in 30 to 40 yr olds, but the incidence peaks in adolescent and preadolescent boys. CT with contrast medium enhancement and MRI are part of the initial evaluation; arteriography, embolization, and extensive surgery may be needed.

Surgical intervention may also be needed for bleeding from the internal maxillary artery or other vessels that may cause bleeding in the posterior nasal cavity.

Other Acquired Abnormalities of the Nose.

Many acquired abnormalities of the nose and paranasal sinuses, such as tumors and septal perforations, present as epistaxis; midface trauma with a nasal or facial fracture may be accompanied by epistaxis. Trauma to the nose can cause a septal hematoma to form; if treatment is delayed, this may lead to death of nasal septal cartilage and a resultant saddle-nose deformity. Other abnormalities that may cause a change in the shape of the nose and paranasal bones, with obstruction but few other symptoms, include fibro-osseus lesions (ossifying fibroma, fibrous dysplasia, and cementifying fibroma) and mucoceles of the paranasal sinuses. These conditions may be suspected on physical examination and confirmed by CT scan and biopsy. Although these are considered benign lesions, they may all greatly change the anatomy of surrounding bony structures and often require surgical intervention for management.

Chapter 363 - Nasal Polyps

Joseph Haddad Jr.

Etiology.

Nasal polyps are benign pedunculated tumors formed from edematous, usually chronically inflamed nasal mucosa. They usually originate from the ethmoidal sinus and present in the middle meatus. Occasionally, they appear within the maxillary antrum and can extend to the nasopharynx (antrochoanal polyp). Large or multiple polyps may completely obstruct the nasal passage. The polyps originating from the ethmoidal sinus are usually smaller and multiple, as compared with the large and usually single antral choanal polyp.

Cystic fibrosis is the most common childhood cause of nasal polyposis and should be suspected in any child younger than age 12 yr with nasal polyps, even in the absence of typical respiratory and digestive symptoms; as many as 30% of children with cystic fibrosis acquire nasal polyps. Nasal polyposis is also associated with chronic sinusitis and allergic rhinitis. In the uncommon *Samter triad*, nasal polyps are associated with aspirin sensitivity and asthma.

Clinical Manifestations.

Obstruction of nasal passages is prominent, with associated hyponasal speech and mouth breathing. Profuse mucoid or mucopurulent rhinorrhea may also be present. An examination of the nasal passages shows glistening, gray, grapelike masses squeezed between the nasal turbinates and the septum. Ethmoidal polyps can be readily distinguished from the well-vascularized turbinate tissue, which is pink or red; antrochoanal polyps may have a more fleshy appearance. Prolonged presence of ethmoidal polyps in a child may widen the bridge of the nose and erode adjacent osseous structures.

Treatment.

Local or systemic decongestants are not usually effective in shrinking the polyps, although they may provide symptomatic relief from the associated mucosal edema. Intranasal steroid sprays, and sometimes systemic steroids, may provide some shrinkage of nasal polyps with symptomatic relief and have proved useful in children with cystic fibrosis. Polyps should be removed surgically if complete obstruction, uncontrolled

rhinorrhea, or deformity of the nose appears. If the underlying pathogenic mechanism cannot be eliminated (e.g., cystic fibrosis), the polyps may soon return. Functional endoscopic sinus surgery may provide more complete polyp removal and treatment of other associated nasal disease; in some cases this has reduced the need for frequent surgeries. Nasal steroid sprays should also be started preventively, once postsurgical healing occurs.

Antral choanal polyps do not respond to medical measures and must be surgically removed. Because these types of polyps are not generally associated with any other underlying disease process, the recurrence rate is much less than for other types of polyps.

Chapter 364 - The Common Cold

Ronald B. Turner
Gregory F. Hayden

The common cold is a viral illness in which the symptoms of rhinorrhea and nasal obstruction are prominent and systemic symptoms and signs such as myalgia and fever are absent or mild. It is often termed *rhinitis* but includes self-limited involvement of the sinus mucosa and is more correctly termed *rhinosinusitis*.

Etiology.

The most common pathogens associated with the common cold are the rhinoviruses (see Chapter 241), but the syndrome may be caused by many different viruses (Table 364–1).

Epidemiology.

Colds occur year round, but the incidence is greatest from the early fall until the late spring, reflecting the seasonal prevalence of the viral pathogens associated with cold symptoms. The highest incidence of rhinovirus infection occurs in the early fall (August–October) and in the late spring (April–May). The seasonal incidence for parainfluenza viruses usually peaks in the late fall, and for respiratory syncytial virus (RSV) and influenza viruses it is highest between December and April.

Young children have an average of six to seven colds per year but 10–15% of children have at least 12 infections per year. The incidence of illness decreases with age, with two to three illnesses per year by adulthood. Children in out-of-home daycare centers during the first year of life have 50% more colds than children cared for only at home. The difference in the incidence of illness between these groups of children decreases as the length of time spent in daycare increases, although the incidence of illness remains higher in the daycare group through at least the first 3 yr of life.

Pathogenesis.

Viruses causing the common cold are spread by small-particle aerosols, large-particle aerosols, and direct contact. Although the different common cold pathogens may presumably be spread by any of these mechanisms, some routes of transmission appear be more efficient than others for particular viruses. Studies of rhinoviruses and RSV suggest that direct contact is an efficient mechanism of transmission of these viruses, although transmission by large particle aerosols may also occur. In contrast to rhinoviruses and RSV, influenza viruses appear to be most efficiently spread by small particle aerosols.

TABLE 364-1 -- **Pathogens Associated with the Common Cold**

Association	Pathogens	Relative Frequency of Colds Caused
Agents primarily associated with colds	Rhinoviruses	Frequent
	Coronaviruses	Occasional
Agents primarily associated with other clinical syndromes that also cause common cold symptoms	Respiratory syncytial virus	Occasional
	Influenza viruses	Uncommon
	Parainfluenza viruses	Uncommon
	Adenoviruses	Uncommon
	Enteroviruses	Uncommon

The respiratory viruses have evolved different mechanisms to avoid host defenses. Infections with rhinoviruses and adenoviruses result in the development of serotype-specific protective immunity. Repeated infections with these pathogens occur because there are a large number of distinct serotypes of each virus. Similarly, influenza viruses have the ability to change the antigens presented on the surface of the virus and thus behave as though there were multiple virus serotypes. The interaction of coronaviruses with host immunity is not well defined, but it appears that there are multiple distinct strains of coronavirus that are capable of inducing at least short-term protective immunity. In contrast, the parainfluenza viruses and RSV each have a small number of distinct serotypes. Re-infection with these viruses occurs because protective immunity to these pathogens does not develop after an infection. Although re-infection is not prevented by the adaptive host response to these viruses, the severity of subsequent illness is moderated by pre-existing immunity.

Viral infection of the nasal epithelium may be associated with destruction of the epithelial lining, as with influenza viruses and adenoviruses, or there may be no apparent histologic damage, as with rhinoviruses, RSV, and coronavirus 229E. Regardless of the histopathologic findings, infection of the nasal epithelium is associated with an acute inflammatory response characterized by release of a variety of inflammatory cytokines and infiltration of the mucosa by inflammatory cells.

This acute inflammatory response appears to be responsible at least in part for many of the symptoms associated with the common cold.

Clinical Manifestations.

The onset of common cold symptoms typically occurs 1–3 days after viral infection. The first symptom noted is frequently sore or “scratchy” throat, followed closely by nasal obstruction and rhinorrhea. The sore throat usually resolves quickly, and by the second and third day of illness nasal symptoms predominate. Cough is associated with approximately 30% of colds and usually begins after the onset of nasal symptoms. Influenza viruses, RSV, and adenoviruses are more likely than are rhinoviruses or coronaviruses to be associated with fever and other constitutional symptoms. The usual cold persists about 1 wk, although 10% last 2 wk.

The physical findings of the common cold are limited to the upper respiratory tract. Increased nasal secretion is frequently obvious to the examiner. A change in the color or consistency of the secretions is common during the course of the illness and is not indicative of sinusitis or bacterial superinfection. Examination of the nasal cavity may reveal swollen, erythematous nasal turbinates, although this finding is nonspecific and of limited diagnostic usefulness.

Diagnosis.

The most important task of the physician caring for a patient with a cold is to exclude other conditions that are potentially more serious or treatable. The differential diagnosis of the common cold includes noninfectious disorders as well as other upper respiratory tract infections (Table 364–2).

Laboratory Findings.

Routine laboratory studies are not helpful for the diagnosis and management of the common cold. A nasal smear for eosinophils may be useful if allergic rhinitis is

TABLE 364-2 -- Conditions That May Mimic the Common Cold

Condition	Differentiating Features
Allergic rhinitis	Prominent itching and sneezing
	Nasal eosinophilia
Foreign body	Unilateral, foul-smelling discharge
	Bloody nasal secretions
Sinusitis	Headache, facial pain, or periorbital edema
	Persistence of rhinorrhea or cough for longer than 10–14 days
Streptococcal asopharyngitis	Nasal discharge that excoriates the nares
Pertussis	Onset of persistent or paroxysmal cough
Congenital syphilis	Persistent rhinorrhea (snuffles) with onset in the first 3 mo of life

suspected. A predominance of polymorphonuclear leukocytes in the nasal secretions is characteristic of uncomplicated colds and does not indicate bacterial superinfection.

The viral pathogens associated with the common cold may be detected by culture, antigen detection, or serologic methods. These studies are generally not indicated in patients with colds because a specific etiologic diagnosis is useful only when treatment with an antiviral agent is contemplated. Bacterial cultures or antigen detection are useful only when group A *Streptococcus*, *Bordetella pertussis*, or nasal diphtheria is suspected. The isolation of other bacterial pathogens is not an indication of bacterial nasal infection and is not a specific predictor of the etiologic agent in sinusitis.

Treatment.

The management of the common cold consists primarily of symptomatic treatment.

ANTIVIRAL TREATMENT.

Specific antiviral therapy is not currently available for rhinovirus infections. Ribavirin, which is approved for treatment of RSV infections, has no role in the treatment of the common cold. The neuraminidase inhibitors oseltamivir and zanamivir have a modest effect on the duration of symptoms associated with influenza virus infections in children. Oseltamivir has also been shown to reduce the frequency of influenza-associated otitis media. The difficulty of distinguishing influenza from other common cold pathogens and the necessity that therapy be started early in the illness (within 48?hr of onset of symptoms) to be beneficial are practical limitations to the use of these agents for mild upper respiratory tract infections. Newer antiviral agents such as pleconaril for treatment of rhinovirus infections are being developed,

although the role, if any, of these agents in routine treatment of the common cold remains to be determined. Antibacterial therapy is of no benefit in the treatment of the common cold.

SYMPTOMATIC TREATMENT.

The use of symptomatic therapies in children has been the subject of some controversy because, although some of these medications have been found to be effective in adults, no studies have demonstrated a significant effect in children. The studies in children are limited because assessment of common cold therapies generally relies on subjective and objective measurements that require the cooperation of the research subject. Young children cannot assist in these measurements so studies of these treatments in children have generally been based on observations by parents or other observers. Until more definitive results are available, the use of symptomatic therapies in children can only be based on an assumption that the effects of symptomatic treatments may be similar in adults and children. A decision to use these medications in children must be balanced against the potential adverse effects of each drug. The prominent or most bothersome symptoms of colds vary during the course of the illness and, therefore, if symptomatic treatments are used, it is reasonable to target therapy to specific bothersome symptoms. If symptomatic treatments are recommended, care should be taken to assure that caregivers understand the intended effect and can determine the proper dosage of the medications.

Fever. Fever is infrequently associated with an uncomplicated common cold and antipyretic treatment is generally not indicated.

Nasal Obstruction. Either topical or oral adrenergic agents may be used as nasal decongestants. Effective topical adrenergic agents such as xylometazoline, oxymetazoline, or phenylephrine are available as either intranasal drops or nasal sprays. Reduced-strength formulations of these medications are available for use in younger children, although they are not approved for use in children younger than 2 yr old. Systemic absorption of the imidazolines (e.g., oxymetazoline and xylometazoline) has very rarely been associated with bradycardia, hypotension, and coma. Prolonged use of the topical adrenergic agents should be avoided to prevent the development of **rhinitis medicamentosa,** an apparent rebound effect that causes the sensation of nasal obstruction when the drug is discontinued. The oral adrenergic agents are less effective than the topical preparations and are associated with systemic effects such as central nervous system stimulation, hypertension, and palpitations.

Rhinorrhea. The first-generation antihistamines reduce rhinorrhea by 25–30%. The effect of the antihistamines on rhinorrhea appears to be related to the anticholinergic rather than the antihistaminic properties of these drugs and therefore the second-generation or “nonsedating” antihistamines have no effect on common cold symptoms. The major adverse effect associated with the use of the antihistamines is sedation, although there is some evidence that this adverse effect is less bothersome in children than in adults. Rhinorrhea may also be treated with ipratropium bromide, a topical anticholinergic agent. This drug produces an effect comparable to the antihistamines but is not associated with sedation. The most common side effects of ipratropium are nasal irritation and bleeding.

Sore Throat. The sore throat associated with colds is generally not severe, but treatment with mild analgesics is occasionally indicated, particularly if there is associated myalgia or headache. The use of acetaminophen during rhinovirus infection has been associated with suppression of neutralizing antibody responses, but this observation has no apparent clinical significance. Aspirin should not be given to children with respiratory infections because of the risk of Reye syndrome in children with influenza.

Cough. Cough suppression is generally not necessary in patients with colds. Cough in some patients appears to be due to upper respiratory tract irritation associated with postnasal drip. Cough in these patients is most prominent during the time of greatest nasal symptoms, and treatment with a first-generation antihistamine may be helpful. In other patients, cough may be a result of virus-induced reactive airway disease. These patients may have cough that persists for days to weeks after the acute illness and may benefit from bronchodilator therapy. Studies of codeine or dextromethorphan hydrobromide have failed to show an effect of these agents on cough in colds. Expectorants such as guaifenesin are not effective antitussive agents.

INEFFECTIVE TREATMENTS.

Many common cold remedies popularized in both the lay and the medical press have no significant effect on cold symptoms in carefully controlled studies. *Vitamin C, guaifenesin*, and *inhalation of warm, humidified air* have all been found to be no more effective than placebo for the symptomatic treatment of colds.

Zinc, given as oral lozenges, has been evaluated in several studies as a treatment for common cold symptoms. The function of the rhinovirus 3C protease, an essential enzyme for rhinovirus replication, is inhibited by zinc, but there has been no evidence of an antiviral effect of zinc in vivo. The effect of zinc on symptoms has been inconsistent, with some studies reporting dramatic treatment effects whereas other studies find no

beneficial effect. A synthesis of these disparate results is difficult, but it appears unlikely that zinc has a clinically significant impact on common cold symptoms.

Echinacea is a popular herbal treatment for the common cold. Although echinacea extracts have been shown to have biologic effects, the effectiveness of echinacea as a common cold treatment has not been adequately studied. The lack of standardization of commercial products containing echinacea presents a formidable obstacle to the rational evaluation or use of this therapy. Until these problems are resolved there is insufficient evidence to support a recommendation of echinacea as a common cold treatment.

Complications.

The most common complication of a cold is *otitis media*, which is reported in 5–30% of children who have a cold, with the higher incidence occurring in children cared for in a group daycare setting. Symptomatic treatment has no effect on the development of acute otitis media, but treatment with oseltamivir reduced the incidence of otitis media from 19% to 9% in patients with influenza.

Sinusitis also appears to be a relatively frequent complication of the common cold (see Chapter 365). Self-limited sinus involvement is a part of the pathophysiology of the common cold, but 0.5–2% of viral upper respiratory tract infections in adults, and 5–13% in children, are complicated by acute bacterial sinusitis. The differentiation of common cold symptoms from bacterial sinusitis may be difficult. The diagnosis of bacterial sinusitis should be considered if rhinorrhea or daytime cough persists without improvement for at least 10–14 days or if signs develop of more severe sinus involvement such as fever, facial pain, or facial swelling. There is no evidence that symptomatic treatment of the common cold alters the frequency of development of bacterial sinusitis.

Exacerbation of *asthma* is a relatively uncommon but potentially serious complication of colds. The majority of asthma exacerbations in children are associated with the common cold. There is no evidence that treatment of common cold symptoms prevents this complication.

Although not a complication, another important consequence of the common cold is the inappropriate use of antibiotics for these illnesses and the associated contribution to the problem of increasing antibiotic resistance of pathogenic respiratory bacteria. In the United States in 1998 there were an estimated 25 million primary care office visits for the common cold, with 30% of these visits resulting in a prescription for antibiotics.

Prevention.

Chemoprophylaxis or immunoprophylaxis is generally not available for the common cold. Immunization or chemoprophylaxis against influenza may be useful for prevention of colds caused by this pathogen; however, influenza is responsible for only a small proportion of all colds. Both vitamin C and echinacea have been reported to prevent the common cold but no significant effect has been detected in carefully controlled studies.

Colds can be prevented by interrupting the chain involved in the spread of virus by direct contact. In the hospital setting, prevention of transmission of respiratory viruses has been achieved by personnel wearing protective face shields to prevent hand-to-eye or hand-to-nose contact. Prevention of the spread of viruses by direct contact can be most readily accomplished by good handwashing by the infected individual and/or the susceptible contact.

Chapter 365 - Sinusitis

Diane E. Pappas
J. Owen Hendley

Sinusitis is a common illness of childhood and adolescence with significant morbidity and the potential for serious complications. There are two types of acute sinusitis: viral and bacterial. The common cold produces a viral, self-limited rhinosinusitis (see Chapter 364). One-half to 2% of viral upper respiratory tract infections in children and adolescents are complicated by acute bacterial sinusitis. Some children with underlying predisposing conditions may have chronic sinus disease that does not appear to be infectious. The means for appropriate diagnosis and optimal treatment of sinusitis remain controversial.

Both the ethmoidal and maxillary sinuses are present at birth, but only the ethmoidal sinuses are pneumatized. The maxillary sinuses are not pneumatized until 4 yr of age. The sphenoidal sinuses are present by 5 yr of age, whereas the frontal sinuses begin development at age 7–8 yr and are not completely developed until adolescence. The ostia draining the sinuses are narrow (1–3?mm) and drain into the **ostiomeatal complex** in the middle meatus. The paranasal sinuses are normally sterile, maintained by the mucociliary clearance system.

Etiology.

The bacterial pathogens causing acute bacterial sinusitis in children and adolescents include *Streptococcus pneumoniae* (about 30%), nontypable *Haemophilus influenzae* (about 20%), and *Moraxella catarrhalis* (about 20%). At present, approximately 50% of *H. influenzae* and 100% of *M. catarrhalis* are ß-lactamase positive. About 25% of *S. pneumoniae* may be penicillin resistant. *Staphylococcus aureus*, other streptococci, and anaerobes are uncommon causes of acute bacterial sinusitis in children. *H. influenzae*, a-hemolytic streptococci, *M. catarrhalis*, *S. pneumoniae*, and coagulase-negative staphylococci are commonly recovered from children with chronic sinus disease.

Epidemiology.

Acute bacterial sinusitis may occur at any age. Predisposing conditions include viral upper respiratory tract infections (which in turn are associated with out-of-home daycare or a school-aged sibling), allergic rhinitis, and cigarette smoke exposure. Children with immune deficiencies, cystic fibrosis, ciliary dysfunction, abnormalities of phagocyte function, gastroesophageal reflux, anatomic defects (e.g., cleft palate), nasal polyps, and nasal foreign bodies (including nasogastric tubes) may develop chronic sinus disease.

Pathogenesis.

Acute bacterial sinusitis typically follows a viral upper respiratory tract infection. Initially, the viral infection produces a viral rhinosinusitis; CT scans have demonstrated fluid in the sinuses during the normal course of the common

cold in healthy young adults. Nose blowing has been demonstrated to generate sufficient force to propel nasal secretions into the sinus cavities. Bacteria from the nasopharynx that enter the sinuses are normally cleared readily, but during viral rhinosinusitis the inflammation and edema may block sinus drainage and impair mucociliary clearance of bacteria. The growth conditions are favorable, and high titers of bacteria are produced.

Clinical Manifestations.

Children and adolescents with sinusitis may present with nonspecific complaints, including nasal congestion, nasal discharge (unilateral or bilateral), fever, and cough. Less common symptoms include bad breath (halitosis), a decreased sense of smell, and periorbital edema. Complaints of headache and facial pain are rare in children. Physical examination may reveal mild erythema and swelling of the nasal mucosa with nasal discharge. Sinus tenderness may be detectable in adolescents and adults.

Diagnosis.

The clinical diagnosis of acute bacterial sinusitis is based solely on history. Persistent symptoms of upper respiratory tract infection, including nasal discharge and cough, for longer than 10–14 days without improvement, or severe respiratory symptoms, including temperature of at least 102°F (39°C) and purulent nasal discharge for 3–4 consecutive days, are suggestive of a complicating acute bacterial sinusitis. Bacteria were recovered from maxillary sinus aspirates in 70% of children with such persistent or severe symptoms studied. Children with **chronic sinusitis** have a history of persistent respiratory symptoms, including cough, nasal discharge, or nasal congestion, lasting more than 90 days.

Sinus aspirate culture is the only accurate method of diagnosis but is not practical for routine use. **Transillumination** of the sinus cavities may demonstrate the presence of fluid but cannot reveal whether it is viral or bacterial in origin. In children, transillumination is difficult to perform and has been shown to be unreliable. Findings on radiographic studies (e.g., sinus plain films and CT scans) including **opacification**, **mucosal thickening,** or presence of an **air-fluid level** are not diagnostic. Such findings can confirm the presence of sinus inflammation but cannot

be used to differentiate between viral, bacterial, or allergic causes of inflammation.

Given the nonspecific clinical picture, differential diagnostic considerations include viral upper respiratory tract infection, allergic rhinitis, nonallergic rhinitis, and nasal foreign body. Viral upper respiratory tract infections are characterized by nasal discharge, cough, and initial fever; symptoms do not usually persist beyond 10–14 days. Allergic rhinitis may be seasonal; evaluation of nasal secretions should reveal significant eosinophilia.

Treatment.

It is unclear whether antimicrobial treatment of clinically diagnosed acute bacterial sinusitis offers any substantial benefit. A recent randomized, placebo-controlled trial comparing 14-day treatment of children with clinically diagnosed sinusitis with amoxicillin, amoxicillin-clavulanate, or placebo found that antimicrobial therapy did not affect symptom resolution, duration of symptoms, or days missed from school. However, the current guidelines from the American Academy of Pediatrics recommend antimicrobial treatment for acute bacterial sinusitis to promote resolution of symptoms and prevent suppurative complications, although 50–60% of children with acute bacterial sinusitis will recover without antimicrobial therapy. Initial therapy with amoxicillin (45?mg/kg/day) is adequate for the majority of children with uncomplicated acute bacterial sinusitis. Alternative treatments for the penicillin-allergic patient include cefuroxime axetil, cefpodoxime, clarithromycin, or azithromycin. For children with risk factors (i.e., antibiotic treatment in the preceding 1–3 mo, daycare attendance, or age younger than 2 yr) for the presence of resistant bacterial species, and for children who fail to respond to initial therapy with amoxicillin within 72?hr, treatment with “high dose” amoxicillin-clavulanate (80–90?mg/kg/day of amoxicillin and 6.4?mg/kg/day of clavulanate) should be initiated. Failure to respond to this regimen necessitates referral to an otolaryngologist for further evaluation because maxillary sinus aspiration for culture and susceptibility testing may be necessary. The appropriate duration of therapy for sinusitis has yet to be determined; individualization of therapy is a reasonable approach, with treatment recommended for 7 days after resolution of symptoms.

Frontal sinusitis can rapidly progress to serious intracranial complications and necessitates initiation of parenteral ceftriaxone until substantial clinical improvement is achieved. Treatment is then completed with oral antibiotic therapy.

The use of decongestants, antihistamines, mucolytics, and intranasal corticosteroids has not been adequately studied in children and is not recommended for the treatment of acute bacterial sinusitis. Likewise, saline nasal washes or nasal sprays may help to liquefy secretions and act as a mild vasoconstrictor, but the effects have also not been systematically evaluated in children.

Complications.

Because of the close proximity of the paranasal sinuses to the brain and eyes, serious orbital and/or intracranial complications may result from acute bacterial sinusitis and progress rapidly. Orbital complications, including periorbital cellulitis and orbital cellulitis, are most often secondary to acute bacterial ethmoiditis. Infection may spread directly through the lamina papyracea, the thin bone that forms the lateral wall of the ethmoidal sinus. **Periorbital cellulitis** produces erythema and swelling of the tissues surrounding the globe, whereas **orbital cellulitis** involves the intraorbital structures and produces proptosis, chemosis, decreased visual acuity, double vision and impaired extraocular movements, and eye pain. Evaluation should include CT scan of the orbits and sinuses with ophthalmology and otolaryngology consultations. Treatment with intravenous antibiotics should be initiated. Orbital cellulitis may require surgical drainage of the ethmoidal sinuses.

Intracranial complications may include meningitis, cavernous sinus thrombosis, subdural empyema, epidural abscess, and brain abscess. Children with altered mental status, nuchal rigidity, or signs of increased intracranial pressure (headache and vomiting) require immediate CT scan of the brain, orbits, and sinuses to evaluate for the presence of intracranial complications of acute bacterial sinusitis. Treatment with broad-spectrum intravenous antibiotics (usually cefotaxime or ceftriaxone combined with vancomycin) should be initiated immediately pending culture and susceptibility results. Abscesses may require surgical drainage. Other complications include osteomyelitis of the frontal bone **(Pott puffy tumor),** which is characterized by edema and swelling of the forehead, and **mucoceles**, which are chronic inflammatory lesions commonly located in the frontal sinuses that can expand, causing displacement of the eye with resultant diplopia. Surgical drainage is usually required.

Prevention.

Prevention is best accomplished by frequent handwashing and avoiding persons with colds. Because acute bacterial sinusitis may complicate influenza infection, prevention of influenza infection by yearly influenza vaccine will prevent some cases of complicating sinusitis. Immunization or chemoprophylaxis against influenza with oseltamivir or zanamivir may be useful for prevention of colds caused by this pathogen and the associated complications; however, influenza is responsible for only a small proportion of all colds.

Chapter 366 - Acute Pharyngitis

Gregory F. Hayden
Ronald B. Turner

Upper respiratory tract infections account for a substantial proportion of visits to pediatricians. Approximately one third of such illnesses feature sore throat as the primary symptom.

Etiology.

The most important agents causing pharyngitis are viruses and group A ß-hemolytic *Streptococcus* (GABHS). Other organisms sometimes associated with pharyngitis include group C *Streptococcus*, *Arcanobacterium haemolyticum*, *Francisella tularensis, Mycoplasma pneumoniae, Neisseria gonorrhoeae*, and *Corynebacterium diphtheriae*. Other bacteria, such as *Haemophilus influenzae* and *Streptococcus pneumoniae*, may be cultured from the throats of children with pharyngitis, but their role in causing pharyngitis has not been established.

Epidemiology.

Viral upper respiratory tract infections occur most commonly in winter and spring and are spread by close contact. Streptococcal pharyngitis is uncommon before 2–3 yr of age. The incidence increases among children and then declines in late adolescence and adulthood. It occurs throughout the year but is reported most often during winter and spring. Illness often spreads among siblings and classmates. Pharyngitis from group C *Streptococcus* and *A. haemolyticum* occurs most frequently among adolescents and adults.

Pathogenesis.

Colonization of the pharynx by GABHS may result in either asymptomatic carriage or acute infection. The **M protein** is the major virulence factor of GABHS and facilitates resistance to phagocytosis by polymorphonuclear neutrophils. Type-specific immunity develops during infection and provides protective immunity to subsequent infection with that particular M serotype.

Scarlet fever is caused by GABHS that produces one of three **streptococcal**

pyrogenic exotoxins (SPEs)—A, B, and C—that can induce a fine papular rash. SPE-A appears to be most strongly associated with scarlet fever. Exposure to each SPE confers specific immunity only to that toxin, and therefore scarlet fever can occur up to three times.

Clinical Manifestations.

The onset of streptococcal pharyngitis is often rapid with prominent sore throat and fever. Headache and gastrointestinal symptoms are frequent. The pharynx is red, and the tonsils are enlarged and classically covered with a yellow, blood-tinged exudate. There may be petechiae or "doughnut" lesions on the soft palate and posterior pharynx, and the uvula may be red, stippled, and swollen. The anterior cervical lymph nodes are enlarged and tender. Some patients demonstrate the additional stigmata of scarlet fever: circumoral pallor, strawberry tongue, and a red, finely papular rash that feels like sandpaper and resembles sunburn with goose pimples.

The onset of viral pharyngitis may be more gradual, and symptoms more often include rhinorrhea, cough, and diarrhea. Adenovirus pharyngitis may feature concurrent conjunctivitis and fever **(pharyngoconjunctival fever).** Coxsackievirus pharyngitis may produce small (1–2?mm), grayish vesicles and punched-out ulcers in the posterior pharynx **(herpangina),** or small (3–6?mm), yellowish white nodules in the posterior pharynx **(acute lymphonodular pharyngitis).** In Epstein-Barr virus (EBV) pharyngitis, there may be prominent tonsillar enlargement with exudate, cervical lymphadenitis, hepatosplenomegaly, rash, and generalized fatigue as part of the infectious mononucleosis syndrome. Primary herpes simplex virus infections in young children often present as high fever and gingivostomatitis.

The illnesses attributed to group C *Streptococcus* and *A. haemolyticum* are generally similar to those caused by GABHS. Infections with *A. haemolyticum* are sometimes accompanied by a blanching, erythematous, maculopapular rash. Gonococcal pharyngeal infections are usually asymptomatic but can cause acute pharyngitis with fever and cervical lymphadenitis.

Diagnosis.

The goal of specific diagnosis is to identify GABHS infection. The clinical presentations of streptococcal and viral pharyngitis show considerable overlap. Physicians using clinical judgment often overestimate the likelihood of a streptococcal etiology, so laboratory testing is useful to identify children who are most likely to benefit from antibiotic therapy. Throat culture remains an imperfect gold standard for diagnosing streptococcal pharyngitis. False-positive cultures can occur if other organisms are misidentified as GABHS, and children who are streptococcal carriers may also have positive cultures. False-negative cultures are attributed to a variety of causes, including an inadequate throat swab specimen and patients' surreptitious use of antibiotic. The specificity of rapid tests to detect group A streptococcal antigen is high, so if a rapid test is positive, throat culture is unnecessary and appropriate treatment is indicated. Rapid tests are generally less sensitive than culture, however, so that confirming a negative rapid test with a throat culture is recommended, especially if the clinical suspicion of GABHS is high. Special culture media and a prolonged incubation are required to detect *A. haemolyticum*. Viral cultures are often unavailable and are generally too expensive and slow to be clinically useful. A complete blood cell count (CBC) showing many atypical lymphocytes and a positive slide agglutination (or "spot") test can help to confirm a clinical diagnosis of EBV infectious mononucleosis.

Treatment.

Most untreated episodes of streptococcal pharyngitis resolve uneventfully in a few days, but early antibiotic therapy hastens clinical recovery by 12–24?hr. The primary benefit of treatment is the prevention of acute rheumatic fever, which is almost completely successful if antibiotic treatment is instituted within 9 days of illness. Antibiotic therapy should be started immediately without culture for children with symptomatic pharyngitis and a positive rapid streptococcal antigen test; clinical diagnosis of scarlet fever; a household contact with documented streptococcal pharyngitis; a past history of acute rheumatic fever; or a recent history of acute rheumatic fever in a family member.

A variety of antimicrobial agents are effective. GABHS remains universally susceptible to penicillin, which has a narrow spectrum and few adverse effects. Penicillin V is inexpensive and is given bid or tid for 10 days: 250?mg/dose for children and 250–500?mg/dose for adolescents and adults. Oral amoxicillin is often preferred for children because of taste and

---

availability as chewable tablets. Studies suggest that a once-daily 750?mg dose of amoxicillin given orally for 10 days is as effective as 250?mg of penicillin given tid for 10 days. Another study suggests that a shorter, 6 day course of oral amoxicillin (50?mg/kg/day divided bid) is as effective as a 10 day course of penicillin V given tid. If confirmed, these advantages will make amoxicillin an even more popular option. A single intramuscular dose of benzathine penicillin (600,000?U for children < 27?kg [60?lb]; 1.2 million U for larger children and adults), or a benzathine-procaine penicillin G combination, is painful but assures compliance and provides adequate blood levels for more than 10 days. Erythromycin (erythromycin ethyl succinate 40?mg/kg/day divided tid or qid orally for 10 days; or erythromycin estolate 20–40?mg/kg/day divided bid, tid, or qid orally for 10 days) is recommended for patients allergic to ß-lactam antibiotics. Reports that a high proportion of patients treated with oral or intramuscular penicillin remain culture positive after treatment deserve further evaluation. Based on the proportion of cultures that remain positive for GABHS after therapy, some drugs (e.g., first-generation cephalosporins) appear to be as good as, or better than, penicillin, perhaps because these drugs are more effective in eradicating streptococcal carriage. Some newer drugs such as azithromycin offer the convenience of once-daily administration or shorter length of therapy, which may improve compliance, but these drugs are generally more expensive than penicillin and have more frequent adverse effects. Evidence is not sufficient to recommend shorter courses of cephalosporins for routine therapy at this time.

Follow-up cultures are unnecessary unless symptoms recur. Some treated patients continue to harbor GABHS in their pharynx and become streptococcal carriers.

Carriage generally poses little risk to patients and their contacts, but it may confound the test results used to determine the etiology of subsequent episodes of sore throat. The treatment regimen most effective for eradicating streptococcal carriage is clindamycin, 20?mg/kg/day divided in three doses (adult dose: 150–300?mg tid) orally for 10 days

Specific therapy is unavailable for most viral pharyngitis. On the basis of in vitro susceptibility data, oral penicillin is often suggested for patients with group C streptococcal isolates and oral erythromycin is recommended for patients with *A. haemolyticum*, but the clinical benefit of such treatment is uncertain.

Nonspecific, symptomatic therapy can be an important part of the overall treatment plan. An oral antipyretic/analgesic agent (e.g., acetaminophen or ibuprofen) may relieve fever and sore throat pain. Gargling with warm salt water is often comforting, and anesthetic sprays and lozenges (often containing benzocaine, phenol, or menthol) may provide local relief.

RECURRENT PHARYNGITIS.

Recurrent streptococcal pharyngitis may represent relapse with an identical strain. If antibiotic compliance has been poor, intramuscular benzathine penicillin is suggested. The possibility of resistance should be considered if a nonpenicillin treatment such as erythromycin was given. Recurrences may also be caused by a different strain resulting from new exposures or may represent pharyngitis of another cause accompanied by streptococcal carriage. This last possibility is likely if the illnesses are mild and otherwise atypical for streptococcal pharyngitis. If GABHS is detected by repeat culture a few days after completing treatment, therapy to eliminate carriage is recommended.

Tonsillectomy lowers the incidence of pharyngitis for 1–2 yr among children with recurrent, culture-positive, GABHS pharyngitis that has been severe and frequent (more than seven episodes in the previous year, or more than five in each of the preceding 2 yr). Most children spontaneously have fewer episodes over time, however, so the anticipated clinical benefit must be balanced against the risks of anesthesia and surgery. Undocumented histories of recurrent pharyngitis are an inadequate basis for recommending tonsillectomy.

Complications and Prognosis.

Viral respiratory tract infections may predispose to bacterial middle ear infections. The complications of streptococcal pharyngitis include local suppurative complications, such as parapharyngeal abscess, and later nonsuppurative illnesses, such as acute rheumatic fever and acute postinfectious glomerulonephritis (see Chapter 168.1).

Prevention.

Multivalent streptococcal vaccines based on M protein peptides are under development. Antimicrobial prophylaxis with daily oral penicillin prevents recurrent GABHS infections but is recommended only to prevent recurrences of acute rheumatic fever (see Chapter 168.1).

Chapter 367 - Retropharyngeal Abscess, Lateral Pharyngeal (Parapharyngeal) Abscess, and Peritonsillar Cellulitis/Abscess

Diane E. Pappas
J. Owen Hendley

The neck contains deeply located lymph nodes including retropharyngeal nodes and lateral pharyngeal nodes that drain the mucosal surfaces of the upper airway and digestive tracts. These nodes lie within the retropharyngeal space (located between the pharynx and the cervical vertebrae and extending down into the superior mediastinum) and the lateral pharyngeal space (bounded by the pharynx medially, the carotid sheath posteriorly, and the muscles of the styloid process laterally), which are interconnected. The lymph nodes in these deep neck spaces communicate with each other, allowing bacteria from either cellulitis or node abscess to spread to other nodes. Infection of the nodes usually occurs as a result of extension from a localized infection of the oropharynx. Retropharyngeal abscess may result from penetrating trauma to the oropharynx, dental infection, and vertebral osteomyelitis. Once infected, the nodes may progress through three stages: cellulitis, phlegmon, and abscess. Infection in the retropharyngeal and lateral pharyngeal spaces may result in airway compromise or posterior mediastinitis, making timely diagnosis important.

Retropharyngeal and Lateral Pharyngeal Abscess.

Retropharyngeal abscess occurs most commonly in children younger than 3–4 yr of age, with boys affected more often than girls. The retropharyngeal nodes involute after 5 yr of age, and therefore infection in older children and adults is much less common.

Clinical manifestations of retropharyngeal abscess are nonspecific and include fever, irritability, decreased oral intake, and

drooling. Neck stiffness, torticollis, and refusal to move the neck may also be present. The verbal child may complain of sore throat and neck pain. Other signs may include muffled voice, stridor, and respiratory distress. Physical examination may reveal bulging of the posterior pharyngeal wall, although this is present in less than 50% of infants with retropharyngeal abscess. Cervical lymphadenopathy may also be present. Lateral pharyngeal abscess commonly presents as fever, dysphagia, and a prominent bulge of the lateral pharyngeal wall, sometimes with medial displacement of the tonsil.

The *differential diagnosis* includes acute epiglottitis and foreign body aspiration. In the young child with limited neck mobility, meningitis must also be considered. Other possibilities include lymphoma, hematoma, and vertebral osteomyelitis.

Incision for drainage and culture of an abscessed node provides the definitive diagnosis, but CT can be useful to identify the presence of a retropharyngeal or lateral pharyngeal abscess (Fig. 367–1). Soft tissue neck films taken during inspiration with the neck extended may show increased width or an air-fluid level in the retropharyngeal space. CT with contrast medium enhancement may reveal central lucency, ring enhancement, or scalloping of the walls of a lymph node.

Retropharyngeal and lateral pharyngeal infections are most often polymicrobial; the usual pathogens include group A *Streptococcus*, oropharyngeal anaerobic bacteria, and *Staphylococcus aureus*. Studies have documented an increased incidence of group A *Streptococcus* recovered from such abscesses. Other pathogens may include *Haemophilus influenzae*, *Klebsiella*, and *Mycobacterium avium-intracellulare*.

Treatment options include intravenous antibiotics with or without surgical drainage. A third-generation cephalosporin combined with ampicillin-sulbactam or clindamycin to provide anaerobic coverage is effective. Studies have shown that more than 50% of children with retropharyngeal or lateral pharyngeal abscess as identified by CT can be successfully treated without surgical drainage. Drainage is necessary, however, in the patient with respiratory distress or failure to improve with intravenous antibiotic treatment. The optimal duration of treatment is unknown, but therapy for several days with intravenous antibiotics until the patient has begun to improve followed by a course of oral antibiotic is typically utilized.

Figure 367-1 Retropharyngeal abscess in a 7-mo-old boy, with associated cellulitis and another involved node in the right lateral neck. The abscess was successfully treated with surgical drainage and antibiotics.

Complications of retropharyngeal or lateral pharyngeal abscess include significant upper airway obstruction, rupture leading to aspiration pneumonia, and extension to the mediastinum. Thrombophlebitis of the internal jugular vein and erosion of the carotid artery sheath may also occur.

An uncommon but characteristic infection of the parapharyngeal space is **Lemierre disease,** in which infection from the oropharynx extends to cause septic thrombophlebitis of the internal jugular vein and metastatic abscesses in the lungs. The causative pathogen is *Fusobacterium necrophorum*, an anaerobic bacterial constituent of the oropharyngeal flora. The typical presentation is that of a previously healthy adolescent or young adult with a history of recent pharyngotonsillar disease who becomes acutely ill with fever and pulmonary symptoms. Chest radiography demonstrates multiple cavitary nodules, often bilateral, and often accompanied by

pleural effusion. Blood culture may be positive. Treatment involves prolonged intravenous antibiotic therapy with penicillin or cefoxitin; surgical drainage of extrapulmonary metastatic abscesses may be necessary.

Peritonsillar Cellulitis/Abscess.

Peritonsillar cellulitis/abscess, which is relatively common compared with the deep neck infections, is caused by bacterial invasion through the capsule of the tonsil, leading to cellulitis and/or abscess formation in the surrounding tissues. The typical patient with a peritonsillar abscess is an adolescent with a recent history of acute pharyngotonsillitis. *Clinical manifestations* include sore throat, fever, trismus, and dysphagia. Physical examination reveals an asymmetric tonsillar bulge with displacement of the uvula. An asymmetric tonsillar bulge is diagnostic, but it may be poorly visualized because of trismus. CT is helpful to reveal the abscess. Group A *Streptococcus* and mixed oropharyngeal anaerobes are the most common pathogens, with more than four bacterial isolates per abscess typically recovered by needle aspiration.

Treatment includes surgical drainage and antibiotic therapy effective against group A *Streptococcus* and anaerobes. Surgical drainage may be accomplished through needle aspiration, incision and drainage, or tonsillectomy. Needle aspiration may involve aspiration of the superior, middle, and inferior aspects of the tonsil to locate the abscess. General anesthesia may be required for the uncooperative patient. Approximately 95% of peritonsillar abscesses resolve after needle aspiration and antibiotic therapy. A small percentage of these patients require a repeat needle aspiration. The 5% who fail to resolve after needle aspiration require incision and drainage. Tonsillectomy should be considered if there is failure to improve within 24 hours of antibiotic therapy and needle aspiration, history of recurrent peritonsillar abscess or recurrent tonsillitis, or complications from peritonsillar abscess. The feared, albeit rare, complication is rupture of the abscess with resultant aspiration pneumonitis. There is a 10% recurrence risk for peritonsillar abscess.

Chapter 368 - Tonsils and Adenoids

Ralph F. Wetmore

Because of the large number of upper respiratory infections that afflict children, especially young children, infectious and inflammatory processes of the pharynx play a significant role in their health. In this chapter the focus is on diseases of the tonsils and adenoids in children, specifically infection, airway obstruction, and, rarely, neoplastic disease.

Definitions.

Waldeyer ring consists of lymphoid tissue that surrounds the opening of the oral and nasal cavities into the pharynx and includes the palatine tonsils, the pharyngeal tonsil or adenoid, lymphoid tissue surrounding the eustachian tube orifice in the lateral walls of the nasopharynx, the lingual tonsil at the base of the tongue, and scattered lymphoid tissue throughout the remainder of the pharynx but especially behind the posterior pharyngeal pillars and along the posterior pharyngeal wall.

Lymphoid tissue located between the palatoglossal fold (anterior tonsillar pillar) and the palatopharyngeal fold (posterior tonsillar pillar) forms the *palatine tonsil*. This lymphoid tissue is separated from the surrounding pharyngeal musculature by a thick fibrous capsule. The *adenoid* is a single aggregation of lymphoid tissue that occupies the space between the nasal septum and the posterior pharyngeal wall. A thin fibrous capsule separates it from the underlying structures; the adenoid does not contain the complex crypts that are found in the palatine tonsils but rather more simple crypts. Lymphoid tissue at the base of the tongue forms the *lingual tonsil* that also contains simple tonsillar crypts.

Normal Function.

Approximately two thirds of the lymphocytes that make up the lymphoid tissue of Waldeyer ring are B lymphocytes, the remainder being either T lymphocytes or plasma cells (see Chapter 113). The immunologic role of the tonsils and adenoid is to induce secretory immunity and to regulate the production of the secretory immunoglobulins. Situated at the opening of the pharynx to the external environment, the tonsils and adenoid are in a position to provide primary defense against foreign matter. Deep crevices within tonsillar tissue form tonsillar crypts that are lined with squamous epithelium but that have a concentration of lymphocytes at the base of the crypt. Lymphoid tissue of Waldeyer ring is most immunologically active between 4–10 yr of age with a decrease after puberty. No major immunologic deficiency has been demonstrated after removal of either or both of the tonsils and adenoid.

Pathology

ACUTE INFECTION.

Most episodes of acute pharyngotonsillitis are viral (see Chapter 366). Group A ß-hemolytic *Streptococcus* (GABHS) is the most common cause of bacterial infection in the pharynx (see Chapter 168). Additional bacterial organisms may include other ß-hemolytic streptococcal species (i.e., group C), *Staphylococcus aureus,* gram-negative organisms, *Mycoplasma pneumoniae,* and, rarely, *Neisseria gonorrhoeae* and *Corynebacterium diphtheriae.* Oral candidiasis may occur in immunocompromised patients or children who have been treated chronically with antibiotics.

CHRONIC INFECTION.

The tonsils and adenoid may be infected chronically in a polymicrobial manner that may include a high incidence of ß-lactamase–producing organisms. Both aerobic species, such as streptococci and *Haemophilus influenzae,* and anaerobic species, such as *Peptostreptococcus, Prevotella, and Fusobacterium,* predominate. The tonsillar crypts may accumulate desquamated epithelial cells, lymphocytes, bacteria, and other debris, causing cryptic tonsillitis. With time, these cryptic plugs may calcify into tonsillar concretions or tonsillolith.

AIRWAY OBSTRUCTION.

Both the tonsils and adenoid are a major cause of upper airway obstruction in children. Airway obstruction in children is typically manifested in sleep-disordered breathing, including obstructive sleep apnea, obstructive sleep hypopnea, and upper airway resistance syndrome (see Chapter 369).

TONSILLAR NEOPLASM.

Rapid enlargement of one tonsil is highly suggestive of a tonsillar malignancy, typically lymphoma in children.

Clinical Manifestations

ACUTE INFECTION.

Symptoms of GABHS infection include dry throat, malaise, fever and chills, odynophagia, dysphagia, referred otalgia, headache, muscular aches, and enlarged cervical nodes. Signs include dry tongue, erythematous enlarged tonsils, tonsillar or pharyngeal exudate, and enlargement and tenderness of the jugulodigastric lymph nodes. See Chapter 168 and Chapter 366 .

CHRONIC INFECTION.

Children with chronic or cryptic tonsillitis frequently present with halitosis, chronic sore throats, foreign body sensation, or a history of expelling foul-tasting and smelling cheesy lumps. Examination may reveal tonsils of almost any size and frequently they contain copious debris within the crypts. Because the offending organism is not usually GABHS, streptococcal culture is usually negative.

AIRWAY OBSTRUCTION.

In many children the diagnosis of airway obstruction (see Chapter 357 and Chapter 369) may be made by history and physical examination. Daytime symptoms of airway obstruction, secondary to adenotonsillar hypertrophy, include chronic mouth breathing, nasal obstruction, hyponasal speech, hyposmia, decreased appetite, poor school performance, and, rarely, symptoms of right-sided heart failure. Nighttime symptoms consist of loud snoring, choking, gasping, frank apneas, restless sleep, abnormal sleep positions, somnambulism, night terrors, diaphoresis, enuresis, and sleep talking. Large tonsils are typically seen on examination, although the absolute size may not be indicative of the degree of obstruction. The size of the adenoid tissue may be demonstrated on a lateral neck radiograph or with flexible endoscopy. Other signs that may contribute to airway obstruction include the presence of a craniofacial syndrome or hypotonia.

TONSILLAR NEOPLASM.

The rapid unilateral enlargement of a tonsil, especially if accompanied by systemic signs of fever, weight loss, and lymphadenopathy, is highly suggestive of a tonsillar malignancy. The diagnosis of a tonsillar malignancy should also be entertained if the tonsil appears grossly abnormal.

Treatment

MEDICAL MANAGEMENT.

The treatment of acute pharyngotonsillitis is discussed in Chapter 366 . For antibiotic treatment of GABHS see Chapter 168 . Because co-pathogens such as staphylococci or anaerobes may produce ß-lactamase that may inactivate penicillin, the use of cephalosporins or clindamycin may be more efficacious in the treatment of chronic throat infections. Children with cryptic tonsillitis may be able to manually express tonsillolith or debris with either a cotton-tipped applicator or a water jet. Chronically infected tonsillar crypts may be cauterized using silver nitrate.

TONSILLECTOMY.

Tonsillectomy alone is usually performed for recurrent or chronic pharyngotonsillitis. Although there are no strict criteria for number of infections, many

---

experts support the criteria developed for the Children's Hospital of Pittsburgh study: seven or more throat infections treated with antibiotics in the preceding year, five or more throat infections treated in each of the preceding 2 yr, or three or more throat infections treated with antibiotics in each of the preceding 3 yr. Clinical indicators developed by the American Academy of Otolaryngology and Head and Neck Surgery suggest the occurrence of three or more treated infections per year as sufficient to warrant surgical intervention. Tonsillectomy has been shown to be effective in reducing the number of infections and the symptoms of chronic tonsillitis such as halitosis, persistent or recurrent sore throats, and recurrent cervical adenitis. In resistant cases of cryptic tonsillitis, tonsillectomy may be curative. Rarely in children, tonsillectomy may be indicated for biopsy of a unilaterally enlarged tonsil to exclude a neoplasm or to treat recurrent hemorrhage from superficial tonsillar blood vessels.

ADENOIDECTOMY.

Adenoidectomy alone may be indicated for the treatment of chronic nasal infection (chronic adenoiditis), chronic sinus infections that have failed medical management, and recurrent bouts of acute otitis media, including those in children with tympanostomy tubes who suffer from recurrent otorrhea. In addition, adenoidectomy may be helpful in children with chronic or recurrent otitis media with effusion. Adenoidectomy alone may be curative in the management of patients with nasal obstruction, chronic mouth breathing, and loud snoring suggestive of sleep-disordered breathing. Adenoidectomy may also be indicated in those children in whom upper airway obstruction is suspected of causing craniofacial or occlusive developmental abnormalities.

TONSILLECTOMY AND ADENOIDECTOMY.

The criteria for both tonsillectomy and adenoidectomy for recurrent infection are the same as those for tonsillectomy alone. The other major indication for performing both procedures together is upper airway obstruction secondary to adenotonsillar hypertrophy that results in sleep-disordered breathing, failure to thrive, craniofacial or occlusive developmental abnormalities, speech abnormalities, or, rarely, cor pulmonale.

Complications

ACUTE PHARYNGOTONSILLITIS.

The two major complications of untreated GABHS infection are post-streptococcal glomerulonephritis and acute rheumatic fever (see Chapter 503 and Chapter 168 , respectively).

PERITONSILLAR INFECTION.

Peritonsillar infection may occur as either cellulitis or a frank abscess in the region superior and lateral to the tonsillar capsule (see Chapter 367). These infections

usually occur in children with a history of recurrent tonsillar infection and are polymicrobial, including both aerobes and anaerobes. Unilateral throat pain, referred otalgia, drooling, and trismus are presenting symptoms. On examination, the affected tonsil is displaced down and medial by swelling of the anterior tonsillar pillar and palate. The diagnosis of an abscess may be confirmed by CT or by needle aspiration, the contents of which should be sent for culture. See Chapter 367 for treatment.

RETROPHARYNGEAL SPACE INFECTION.

Infections in the retropharyngeal space develop in the lymph nodes that drain the oropharynx, nose, and nasopharynx (see Chapter 367).

PARAPHARYNGEAL SPACE INFECTION.

Tonsillar infection may extend into the parapharyngeal space causing symptoms of fever, neck pain, and neck stiffness and signs of swelling of the lateral pharyngeal wall and neck on the affected side. The diagnosis is confirmed by contrast medium–enhanced CT, and treatment includes intravenous antibiotics and external incision and drainage if an abscess is demonstrated on CT. See Chapter 367 .

CHRONIC PHARYNGOTONSILLITIS.

Because GABHS can be found incidentally in many children, controversy exists over whether to treat those children who have been shown to be carriers. Medical management of streptococcal carriage includes (1) clindamycin (20?mg/kg/day in four divided doses), (2) amoxicillin with clavulanate (40–45?mg/kg/day in two or three divided doses), or (3) penicillin V (250?mg tid for 10 days) plus rifampin (20?mg/kg/day during the last 4 days of treatment). Tonsillectomy is usually also curative.

CHRONIC AIRWAY OBSTRUCTION (also see Chapter 369).

Although rare, children with chronic airway obstruction from enlarged tonsils and adenoids may present with cor pulmonale.

The effects of chronic airway obstruction and mouth breathing on facial growth remain controversial. Studies of chronic mouth breathing, both in humans and animals, have shown changes in facial development, including prolongation of the total anterior facial height and a tendency toward a retrognathic mandible, the so-called adenoid facies. Adenotonsillectomy may reverse some of these abnormalities. Other studies have disputed these findings.

TONSILLECTOMY AND ADENOIDECTOMY.

Bleeding may occur in the immediate postoperative period or may be delayed after separation of the eschar. Swelling of the tongue and soft palate may lead to acute airway obstruction in the first few hours after surgery. Children with underlying hypotonia or craniofacial anomalies are at greater risk to suffer this complication. Dehydration from odynophagia is not uncommon during the first postoperative week.

Rare complications include velopharyngeal insufficiency, nasopharyngeal or oropharyngeal stenosis, and psychological problems.

Chapter 369 - Obstructive Sleep Apnea and Hypoventilation

Carol L. Rosen
Lewis J. Kass
Gabriel G. Haddad

Obstructive sleep apnea and hypoventilation (OSA/H) (see also Chapter 57.3 and Chapter 368) is a common medical problem in adults that is increasingly recognized in children. It is a disorder of breathing during sleep characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep and normal sleep patterns (see Chapter 20.5). If unrecognized and untreated, it can lead to impaired daytime functioning as well as more serious complications, such as heart failure, developmental delay, poor growth, and death.

Etiology.

Anatomic factors that increase resistance to airflow predispose to upper airway collapse and OSA/H. The most common anatomic predisposing condition in children is adenotonsillar hypertrophy. Many other predisposing nasal, pharyngeal, and craniofacial abnormalities occur less frequently (Box 369–1). Functional abnormalities also contribute to OSA/H in children. Even when the structure of the upper airway is normal, if coordinated activation of inspiratory and oropharyngeal dilator muscles do not occur, then OSA/H will develop. The most common functional process contributing to OSA/H is rapid eye movement (REM) sleep, present during one fourth of a typical night's sleep. Apnea frequency, apnea duration, and levels of hypoxemia are almost always more severe during REM sleep in both children and adults with OSA/H. Other functional abnormalities contributing to OSA/H include abnormalities of neural respiratory control and drugs that depress the central nervous system (Box 369–2). Childhood conditions associated with either anatomic and/or functional causes of OSA/H include craniofacial abnormalities (e.g., Pierre Robin sequence and Crouzon and Apert syndromes), genetic syndromes (e.g., trisomy 21), skeletal disorders (e.g., achondroplasia), storage diseases (e.g., Hunter syndrome), children with morbid obesity or Prader-Willi syndrome, and other neurologic disorders (e.g., cerebral palsy). Children with these types of problems should be periodically assessed for the development of signs and symptoms of OSA/H.

Epidemiology.

OSA/H occurs in children of all ages, from newborns to young adults, with estimates of prevalence rates ranging from 0.7–3%. The peak incidence is in the preschool age group (2–5 yr), a period when adenotonsillar tissue is greatest in relationship to airway size. The incidence in males and females is similar in prepubertal children, which is in contrast to OSA/H in adults, where the disorder is more common in males. Among otherwise healthy children, obesity, upper and lower respiratory problems (e.g., chronic rhinitis and asthma), and African-American race are independent risk factors for OSA/H. For obese children in general, the severity of OSA/H correlates with the severity of obesity. Positive family history of OSA/H in another family member(s) also is a risk factor for OSA/H in childhood.

Pathogenesis.

OSA/H occurs when there is failure to maintain upper airway patency, usually during sleep, which in turn affects blood gas homeostasis and sleep continuity. Two

Box 369-1. Anatomic Factors That Predispose to Obstructive Sleep Apnea and Hypoventilation in Children

NOSE

  - Dysphagia
  - Excess oral secretions
  - Obesity
  - Prematurity

hypotheses suggest an explanation for the pathogenesis of OSA/H in children and adults. *The Starling resistor principle* has been proposed to explain the frequent occurrence of partial upper airway obstruction associated with flow limitation. During

inspiratory flow limitation, airflow is determined by pressure-generating changes in resistance upstream (e.g., at the adenoid-palate level) from the collapsible segment (pharynx). Airflow is not augmented by increased negative pressure downstream (esophageal pressure), even when inspiratory pressure-generating muscles contract more forcefully. During inspiration, a negative pressure is generated within the pharynx owing to activation of the diaphragm and intercostal muscles and mucosal adhesion forces. Collapse of the upper airway from the force of this negative pressure is prevented by simultaneous activations of the oropharyngeal dilator muscles such as the genioglossus muscle that protrudes the tongue. According to the *balance of forces hypothesis*, OSA/H occurs when an imbalance in these forces favors negative oropharyngeal pressures during inspiration. Upper airway muscle tone (oropharyngeal muscle) decreases during sleep, then to a greater degree during rapid-eye-movement (REM) sleep, thus explaining the increased vulnerability of the upper airway to collapse during this sleep state.

It is the combination of neuromuscular inactivation (or lack of full activation) superimposed on structural narrowing that contributes to the development of OSA/H. For example, the presence of adenotonsillar hypertrophy does not ordinarily cause airflow obstruction during wakefulness. Decreased airway tone that occurs when a child goes to sleep, superimposed on adenotonsillar hypertrophy, can lead to significant airway obstruction. Conditions that decrease caliber, increase collapsibility, or alter neural control of the upper airway or central ventilatory drive contribute to the development of obstruction, which, in turn, affects blood gas homeostasis and sleep quality. In normal children, arterial oxygen decreases and carbon dioxide increases only slightly during sleep. Episodes of partial or complete airway obstruction result in impaired gas exchange with hypoxemia and hypercapnia. The impaired gas exchange in conjunction with decreased airflow is potent stimuli for increased ventilatory effort and upper airway muscle activity. Arousal from sleep is associated with increased respiratory effort and airway muscle tone, which leads to resumption of airway patency. Arousals may appear in the form of movement, increased muscle tone, or changes in the electroencephalogram (EEG). Following the arousal, airflow is restored, blood gases are normalized, and sleep resumes, but the cycle of airway collapse starts again. Compared with adults with OSA/H, fewer cyclic arousals are seen in children in spite of continued hypoventilation and blood gas disturbances throughout the night. This

may, in part, explain the relatively low incidence of daytime sleepiness in young children with OSA/H.

Although there is no direct correlation between tonsil size and severity of OSA/H, enlarged tonsils and adenoids are still the most common risk factors for OSA/H. Other anatomic factors such as micrognathia, retrognathia, or macroglossia may force the tongue into the oropharyngeal portion of the airway and cause airway occlusion. Fat deposition from morbid obesity or a congenitally small midface or nasopharynx also narrows the airway. Increased resistance from swollen nasal turbinates or choanal stenosis places a greater negative collapsing pressure on the pharyngeal airway and may lead to worsening obstruction. Diminished arousal responses can impair the ability to restore upper airway patency. Children with central nervous system abnormalities associated with impaired ventilatory or arousal responses to hypoxemia, hypercapnia, and/or airflow obstruction (e.g., Chiari II malformations) have increased vulnerability to severe OSA/H and cardiorespiratory failure. Finally, sedative medication or general anesthesia can further compromise neural control of the upper airway.

The development of OSA/H can have serious cardiorespiratory and neurobehavioral consequences. Chronic hypoxemia can lead to polycythemia, growth failure, increased pulmonary artery pressure and pulmonary hypertension, right-sided heart failure, arrhythmias, or even death. Recurrent arousals can lead to sleep fragmentation, loss of normal sleep patterns, and excessive daytime sleepiness. OSA/H has been associated with other daytime sequelae, including inattentiveness and hyperactivity, behavioral problems, impaired school performance, and accidents. Finally, sleep fragmentation itself can suppress arousal responses and further impair the ability to re-establish upper airway patency and restore gas exchange.

Clinical Manifestations.

Common clinical manifestations of OSA/H include chronic mouth breathing, snoring, and restlessness during sleep with or without frequent awakenings. Children may sleep in unusual positions to help maintain a patent upper airway, for example, with the neck hyperextended or prone with the bottom up in the air. Typically, loud snoring is the symptom that most disturbs, and therefore alerts, the parents. Most children with OSA/H breathe normally while awake.

Habitual snoring, the most common symptom of OSA/H, ranges from 3–12% in children. However, not all habitually snoring children have or are at risk for the development of OSA/H. The spectrum of severity (ranging from snoring to congestive heart failure) is related to the degree of upper airway narrowing and resistance, duration of the disease, the presence or absence of hypoxemia episodes, and other sequelae. Primary snoring, upper airway resistance syndrome, obstructive hypoventilation, and OSA represent a spectrum of clinical manifestations associated with increasing severity of upper airway obstruction. However, the majority of children with OSA/H do not present with dramatic, repetitive obstructive apneas terminated by arousals. Instead, OSA/H presents as partial continuous obstructive hypoventilation with fewer discrete obstructive apneas, fewer arousals, and less disturbance of sleep architecture. For this reason, daytime hypersomnolence is much less frequent in children than adults. Because of this more subtle presentation, children often have an unexpected degree of airway obstruction, impairment of gas exchange, and sleep disturbance that is difficult to predict from the clinical history and physical examination alone.

Children with the more severe presentation also have noisy, mildly labored awake breathing that clearly worsens with sleep. Parents describe that cyclically the snoring becomes very loud, followed by silence, a snort, an arousal, and resumption of snoring. When snoring is associated with nocturnal breathing difficulties and witnessed respiratory pauses, this triad of symptoms is highly suggestive of OSA/H in children. However, some children with serious OSA/H have minimal noisy breathing, and diagnosis depends on the physician's high index of suspicion.

Less common symptoms include daytime hypersomnolence resulting from sleep fragmentation that occurs when OSA is repeatedly terminated by arousals. However, it is difficult to recognize excessive sleepiness in young children, who normally have

daytime naps and early bedtimes. Poor school performance is increasingly recognized as being associated with OSA/H. Lower academic performance has been described in young children as well as in adolescents who suffer from OSA/H or from primary snoring. There is debate as to whether these neurocognitive deficits are the result of a poor night's sleep secondary to frequent arousal and hence inability to concentrate in school or the result of spending every night in relative hypoxemia that could be predisposing the child to cerebral ischemia. Additionally, the possible association of inattentiveness, hyperactivity, and behavioral problems with OSA/H highlights the importance of investigating whether unrecognized OSA/H may be playing a role in children diagnosed with attention deficit disorder with hyperactivity (ADHD).

Although obesity is a risk factor for OSA/H in children, most children with OSA/H are not obese. In fact, some children, especially children younger than 3 yr of age, are underweight or present with failure to thrive. Several factors might contribute to this growth retardation: dysphagia from large tonsils, nasal obstruction from enlarged adenoids that interferes with breathing during eating, chronic hypoxemia, higher metabolic expenditure from increased work of breathing, and insufficient growth hormone release in the absence of deep REM sleep. Children may also present with unexplained right-sided heart failure, but other cardiovascular complications, such as systemic hypertension or life-threatening cardiac arrhythmias, are rarely seen, except in the most long-standing and neglected cases. In the more severe cases, a relatively minor respiratory illness or infection can trigger an acute episode of respiratory failure. Finally, secondary enuresis that disappears after surgical relief of the upper airway obstruction is occasionally seen, but the mechanisms are poorly understood.

Clinical examination features associated with OSA/H include dysmorphic facies, mouth breathing, hyponasal speech, macroglossia, cleft palate, or enlarged tonsils. Specific craniofacial anomalies may be apparent. A pectus excavatum deformity can develop in long-standing upper airway obstruction. Morbid obesity mechanically loads the chest wall and narrows the upper airway, but OSA/H is not a consistent feature of obesity. The presence of excessive somnolence during the examination requires urgent evaluation. The presence of stridor or hoarse voice can indicate cranial nerve dysfunction and should prompt a meticulous neurologic examination.

Laboratory Findings.

Polycythemia and respiratory acidosis with a metabolic alkalosis support the diagnosis of OSA/H when present but are absent in the majority of pediatric patients. Right ventricular hypertrophy on electrocardiography and dysfunction on echocardiography are seen only in severe OSA/H. A lateral soft tissue radiograph of the neck can identify adenoidal tissue. When procedures require sedation or anesthesia, extreme caution is required if OSA/H is suspected. Such medications have profound effects on upper airway muscle tone, and sudden respiratory decompensation can occur in these children.

Diagnosis.

The diagnosis is often delayed, despite years of symptoms, for several reasons: (1) there may be absence of awake symptoms; (2) a sleep history was not obtained; (3) symptoms of snoring or restless sleep are considered inconsequential; (4) parents may be unaware of the problem because the child's most severe symptoms appear during REM sleep in the last third of the night when parents are asleep; and (5) young children may not generate the loud, disruptive snoring noises of an adult. The diagnosis should be suggested by the clinical presentation.

Parental reports of habitual snoring should be investigated. A sleep and breathing history is mandatory for any child with a medical condition that is at risk for OSA/H, especially trisomy 21, craniofacial anomalies, achondroplasia, or other neuromuscular disorders.

However, OSA/H cannot be diagnosed from clinical history alone. Snoring, reports of difficulty breathing, and enlarged tonsils can be unreliable predictors of the presence or severity of OSA/H in children. The physical examination performed during wakefulness may be entirely normal and cannot be used to exclude OSA/H when the clinical history suggests otherwise. Pulse oximetry is insensitive. Other diagnostic methods, including audio/videotaping and nap or home polysomnography (PSG), remain investigational techniques. An overnight recording of multiple physiologic sensors during sleep is considered the gold standard for the diagnosis of OSA/H (see Chapter 359). It provides a powerful, quantitative, noninvasive assessment of frequency and severity of sleep-disordered breathing and sleep disruption. PSG is especially useful in confirming the diagnosis, in determining the severity of OSA/H, and in documenting the efficacy of treatment. PSG in children, especially very young or special needs children, requires skilled, well-trained, child-friendly sleep technicians in family-centered environments. However, PSG may not be required for diagnostic purposes in all patients. For example, PSG may not be necessary when a child has noisy, awake mouth breathing and tonsils that occlude most of the pharyngeal space; is excessively sleepy; and is observed by skilled personnel to have signs of airway obstruction and hypoxemia.

PSG can confirm the presence and severity of airflow obstruction. Because patients with severe OSA/H are at increased risk for perioperative and postoperative complications from adenotonsillectomy, prior knowledge of severity can help determine the appropriateness of same-day outpatient surgery vs. overnight in-hospital observation and monitoring. PSG is required to determine the optimal level of continuous positive airway pressure (CPAP) needed to manage OSA/H when adenotonsillectomy is not a therapeutic option. Other children considered “high risk” are those younger than 3 yr of age and children with morbid obesity, craniofacial anomalies, genetic disorders, or other complex medical conditions.

Several other disorders should be considered in the *differential diagnosis* of OSA/H or may coexist with this problem. Occasionally, breathing difficulty associated with nocturnal asthma or upper airway obstruction from gastroesophageal reflux may be confused with OSA/H. New-onset dysphagia and swallowing difficulties associated with an esophageal foreign body that compresses the airway can masquerade as OSA/H. Stridor caused by anatomic airway problems, such as laryngomalacia, vascular ring, intraluminal masses, and vocal cord dysfunction, should be considered. Parasomnia events, such as night terrors or even nocturnal seizures,

may be mistaken for arousals associated with OSA/H. Narcolepsy and periodic limb movement disorder should be considered when PSG fails to document OSA/H in a child with daytime hypersomnolence.

Complications.

Early reports of untreated OSA/H highlighted the most severe cases with sequelae that included failure to thrive, pulmonary hypertension, and/or cor pulmonale. Such severe complications are now rare owing to increased awareness of OSA/H among primary care providers, recognition of high-risk subgroups such as trisomy 21 or craniofacial disorders, and earlier diagnosis and treatment. Many of the children who come to medical attention and consideration of surgical intervention today have much less severe OSA/H and symptoms of shorter duration.

Failure to diagnose and treat OSA/H can result in serious but generally reversible consequences for the child. Whereas the sequelae of cor pulmonale and growth and developmental impairment are well documented, the potential negative impact of OSA/H on neurocognitive and behavioral dysfunction has not been well characterized but may include attentional capacity, memory, and cognitive function and increased behavior problems.

Prevention.

Because obesity is a risk factor for the increased severity of OSA/H, the persistence of OSA/H after adenotonsillectomy, and the development of OSA/H in adulthood, weight management should be a long-term goal in a child at risk or diagnosed with OSA/H.

Treatment.

Adenotonsillectomy is the most common therapy for OSA/H in children with adenotonsillar hypertrophy. However, the treatment for a particular child depends on the underlying abnormalities, the site of obstruction, and the presence or absence of contributing neurologic or functional abnormalities. Box 369–3 lists possible treatments. When adenotonsillar hypertrophy is present, the majority of otherwise healthy children without major risk factors experience resolution or significant improvement after adenotonsillectomy. Children with severe OSA/H who benefit from surgery often demonstrate “catch-up” growth. However, children with underlying problems, such as trisomy 21, craniofacial disorders, extreme obesity, or neuromuscular disorders such as cerebral palsy or Chiari malformation, or who present before 2 yr of age are at risk for incomplete resolution of OSA/H after adenotonsillectomy. Even without these risk factors, the parents and physicians of children who have had adenotonsillectomy should be aware that either persistent or recurring symptoms of OSA/H need re-evaluation, including reassessment for adenoidal regrowth and possible need for repeat adenoidectomy or other treatments.

Medical management with nasal CPAP is an option in children in whom adenotonsillectomy fails, thus avoiding the need for a tracheostomy. CPAP is safe and well tolerated but requires a motivated family for compliance. PSG is required to select the appropriate pressure level to relieve obstruction. Follow-up PSG should be performed at regular intervals because the long-term stability of CPAP requirements in the growing child is not known. CPAP should not be first-line treatment when adenotonsillar hypertrophy is present and there are no absolute contraindications to surgery. CPAP can be useful in the obese child in whom weight loss is desirable but difficult to achieve. Supplemental oxygen may relieve the hypoxemia associated with OSA/H but is clearly insufficient to address the underlying obstruction and hypoventilation. A nasopharyngeal tube may be a short- or long-term adjunct to care in selected patients.

Stenting procedures for nasal stenosis/atresia

Cleft palate revision procedures

Uvulopalatopharyngoplasty

Correction of deviated septum, nasal polypectomy

Tracheostomy

Pharmacologic management has only a limited role in pediatric OSA/H patients. Treatment of nasal obstruction with topical nasal steroids can reduce snoring and OSA/H severity in some children. However, significant residual obstruction from unrelieved adenotonsillar hypertrophy requires adenotonsillectomy for definitive management. Steroids and antibiotics may be a useful adjunct in the acute management of infected pharyngeal tissues that have compromised upper airway patency, but adenotonsillectomy is the definitive management once the acute processes have resolved sufficiently to allow safe surgical management. Medroxyprogesterone acetate augments ventilatory drive and has been used in the management of the daytime hypoventilation associated with the obesity-hypoventilation syndrome. However, this drug fails to improve nocturnal obstructive symptoms and has adverse effects on growth and pubertal development. Protriptyline is a nonsedating antidepressant with REM suppressant activity that has been tried in adult OSA/H patients but is not recommended for children.

If severe upper airway obstruction is present in both wakefulness and sleep, then tracheostomy is the treatment of choice, particularly when vocal cord dysfunction, impaired swallowing, or absent laryngeal protective reflexes exist. Tracheostomy may be necessary for severe OSA/H complicated by cor pulmonale when CPAP is unsuccessful or not tolerated.

There is increasing pediatric experience with treatment by mandibular distraction osteogenesis as an alternative to long-term tracheostomy. Definitive maxillomandibular reconstructive surgery for children with craniofacial disorders is another therapeutic option but is usually postponed until facial growth is complete. Uvulopalatopharyngoplasty, the resection of redundant pharyngeal tissue, has been used to eliminate snoring in adults, but the failure rate is high. Pediatric experience with this surgery has been limited to children with muscular hypotonia and oropharyngeal tissue redundancy, but no controlled studies using objective measures of efficacy have been performed.

Prognosis.

Failure to diagnose and treat OSA/H can result in serious, but generally reversible, consequences for the child, including impaired growth and cardiorespiratory failure. However, the impact of OSA/H and its treatment on neurocognitive and behavioral dysfunction is unknown.

Section 3 - *Disorders of the Lungs and Lower Airways*

Thomas P. Green
Susanna A. McColley

Virtually every child experiences lower respiratory tract disease; for most, the disorder is mild and self-limited as often occurs with viral bronchitis. For a small but growing minority of children, recurrent respiratory disease, such as asthma, produces periods of significant respiratory dysfunction interspersed with times of relatively normal lung function. In a few children, chronic respiratory disease, as seen in cystic fibrosis or primary ciliary dyskinesia, requires constant medical supervision and may dramatically affect the quality and duration of life.

The chapters in this section deal with disorders of the lungs and the large airways below the larynx. Chapters in other sections of this book deal with important topics in lower respiratory tract disease, and this material is not duplicated here. These include acute respiratory distress and respiratory failure (see Chapters 57.3 , 58 , and 357.1), drowning and near-drowning (see Chapter 61), neonatal respiratory tract disorders (see Chapter 90), asthma (see Chapter 134), and sarcoidosis (see Chapter 155). Diseases of other organ systems also may result in pulmonary dysfunction. These issues are considered in this section (see Chapter 411).

Chapter 370 - Chronic or Recurrent Respiratory Symptoms

Thomas F. Boat

Respiratory tract symptoms such as cough, wheeze, and stridor may occur frequently or persist for long periods in a substantial number of children; others may have persistent or recurring lung infiltrates with or without symptoms. Determining the cause of these chronic findings can be difficult because symptoms may be caused by a rapid succession of unrelated acute respiratory tract infections or by a single pathophysiologic process, and there is a paucity of easily performed, specific diagnostic tests for many acute and chronic respiratory conditions. Pressure from the affected child's family for a quick remedy because of concern over symptoms related to breathing may complicate diagnostic and therapeutic efforts.

A systematic approach to the diagnosis and treatment of these children consists of assessing whether the symptoms are the manifestation of a minor problem or a life-threatening process; determining the most likely underlying pathogenic mechanism; selecting the simplest effective therapy for the underlying process, which may often be only symptomatic therapy; and carefully evaluating the effect of therapy. Failure of this approach to identify the process responsible or to effect improvement signals the need for more extensive and perhaps invasive diagnostic efforts, including bronchoscopy.

Judging the Seriousness of Chronic Respiratory Complaints.

Clinical manifestations suggesting that a respiratory tract illness may be life threatening or associated with the potential for chronic disability are listed in Box 370–1 . If none of these findings is detected, the chronic respiratory process is usually benign. For example, active, well-nourished, and appropriately growing infants who present with intermittent noisy breathing but no other physical or laboratory abnormalities require only symptomatic treatment and parental reassurance. However, benign-appearing but persistent symptoms occasionally may be the harbinger of a serious lower respiratory tract problem and, conversely, a few children (e.g., those with infection-related asthma) may have recurrent life-threatening episodes but few or no symptoms in the intervals. Repeated examinations over an extended period, both when the child appears healthy and when the child is symptomatic, are often helpful in sorting out the severity and chronicity of lung disease.

Recurrent or Persistent Cough.

Cough is a reflex response of the lower respiratory tract to stimulation of irritant or cough receptors in the airways' mucosa. The most common cause in children is reactive airways (asthma). Because cough receptors also reside in the pharynx, paranasal sinuses, stomach, and external auditory canal, the source of a persistent cough may need to be sought beyond the lungs. Specific lower respiratory stimuli include excessive secretions, aspirated foreign material, inhaled dust particles or noxious gases, and an inflammatory response to infectious agents or allergic processes. Some of the conditions responsible for chronic cough are listed in Box 370–2 .

Characteristics of cough that may aid in distinguishing its origin are presented in Table 370–1 . Additional useful information may include a history of atopic conditions (e.g., asthma, eczema, urticaria, allergic rhinitis), a seasonal or environmental variation in frequency or intensity of cough, and a strong family history of atopic conditions, all suggesting an allergic cause; symptoms of malabsorption or family history indicative of cystic fibrosis; symptoms related to feeding, suggesting aspiration; a choking episode, suggesting foreign body aspiration; headache or facial

edema associated with sinusitis; and a smoking history in older children and adolescents or the presence of a smoker in the house.

Considerable information pertaining to the cause of chronic cough can be obtained during the *physical examination*. Posterior pharyngeal drainage combined with a nighttime cough suggests chronic upper airway disease such as sinusitis. An overinflated chest suggests chronic airway obstruction, as in asthma or cystic fibrosis. An expiratory wheeze, with or without diminished intensity of breath sounds, strongly suggests asthma or asthmatic bronchitis but may also be consistent with a diagnosis of cystic fibrosis, vascular ring, aspiration of foreign material, or pulmonary hemosiderosis. Careful auscultation during forced expiration may reveal expiratory wheezes that are otherwise undetectable and that are the only indication of underlying

Endobronchial or endotracheal tumors

Endobronchial tuberculosis

Habit cough

Hypersensitivity pneumonitis

Fungal infections

Inhaled irritants, including tobacco smoke

Irritation of external auditory canal

reactive airways. Coarse crackles suggest bronchiectasis, including cystic fibrosis, but may also occur with an acute or subacute exacerbation of asthma. Clubbing of the digits is seen in most patients with bronchiectasis but in only a few other respiratory conditions with chronic cough. Tracheal deviation suggests foreign body aspiration or a mediastinal mass.

It is essential to allow sufficient examination time to detect a spontaneous cough. If not spontaneous, most children by 4–5 yr of age can cough on request. Asking the child to take a maximal breath and forcefully exhale repeatedly usually induces a cough reflex. Children who cough as often as several times a minute with regularity are likely to have a habit (tic) cough. If the cough is loose, every effort should be made to obtain sputum; most older children can comply. It is sometimes possible to pick up small bits of sputum with a throat swab quickly inserted into the lower pharynx while the child coughs with the tongue protruding. Clear mucoid sputum is most often associated with an allergic reaction or asthmatic bronchitis. Cloudy (purulent) sputum

TABLE 370-1 -- **Characteristics of a Chronic Cough and Their Etiologic Significance**

Type of Cough	Likely Responsible Condition
Loose (discontinuous), productive	Bronchitis, asthmatic bronchitis, cystic fibrosis, bronchiectasis
Brassy	Tracheitis, habit cough
With stridor	Laryngeal obstruction, pertussis
Paroxysmal (with or without gagging and vomiting)	Cystic fibrosis, pertussis syndrome, foreign body
Staccato	Chlamydial pneumonitis
Nocturnal	Upper or lower respiratory tract allergic reaction, or both, sinusitis
Most severe on awakening in morning	Cystic fibrosis, bronchiectasis, chronic bronchitis
With vigorous exercise	Exercise-induced asthma, cystic fibrosis, bronchiectasis
Disappears with sleep	Habit cough, mild hypersecretory states such as in cystic fibrosis and asthma
Tight (wheezy)	Reactive airways

suggests a respiratory tract infection but may also reflect increased cellularity (eosinophilia) due to an asthmatic process. Very purulent sputum is characteristic of bronchiectasis. Malodorous expectorations suggest anaerobic infection of the lungs. In cystic fibrosis, the sputum, even when purulent, is rarely foul smelling.

Laboratory tests may help in the evaluation of a chronic cough. Only sputum specimens containing alveolar macrophages should be used for studying lower respiratory tract processes. Sputum eosinophilia suggests asthma, asthmatic bronchitis, or hypersensitivity reactions of the lung, but a polymorphonuclear cell response suggests infection; if sputum is unavailable, the presence of eosinophilia in nasal secretions also suggests atopic disease. If most of the cells in sputum are macrophages, postinfectious hypersensitivity of cough receptors should be suspected. Sputum macrophages can be stained for hemosiderin content, which is diagnostic of pulmonary hemosiderosis, or for lipid content, which in large amounts suggests, but is not specific for, repeated aspiration. Children whose coughs persist longer than 6 wk should be tested for cystic fibrosis. Sputum culture is helpful for diagnosis of cystic fibrosis but less so for other conditions because throat flora may

contaminate the sample.

Hematologic assessment may reveal anemia that is the result of pulmonary hemosiderosis or eosinophilia that accompanies asthma and other hypersensitivity reactions of the lung. Infiltrates on the chest radiograph suggest cystic fibrosis, bronchiectasis, foreign body, hypersensitivity pneumonitis, or tuberculosis. When asthma-equivalent cough is suggested, a trial of bronchodilator therapy may be diagnostic. After the initial evaluation, especially if the cough does not respond to initial therapeutic efforts, more specific diagnostic procedures may be indicated, including an immunologic or allergic evaluation, chest and paranasal sinus imaging, esophagograms, tests for gastroesophageal reflux, special microbiologic studies including rapid viral testing, evaluation of ciliary morphologic features, and bronchoscopy.

Habit cough ("psychogenic cough tic") must be considered in any child with a cough that has lasted for weeks or months, that has been refractory to treatment, that disappears with sleep, and that typically has a harsh, "barking" quality. This cough may be absent if the physician listens outside the examination room but will reliably appear immediately on direct attention to the child and the symptom. It typically begins with an upper respiratory infection but then lingers. The child misses many days of school because the cough disrupts the classroom. This disorder accounts for many unnecessary medical procedures and courses of medication. It is treatable with assurance that a lung pathologic condition is absent and that the child should resume full activity, including school. This assurance, together with speech therapy techniques that allow the child to reduce musculoskeletal tension in the neck and chest and that increase the child's awareness of the initial sensations that trigger cough, has been very successful. This approach does not depend on deception, unlike a reportedly successful technique that involves wrapping the child's chest with a bedsheet to "strengthen weakened muscles" until the coughing stops. The designation "habit cough" is preferable to "psychogenic cough" because it carries no stigma and because most of these children do not have significant emotional problems. When the cough disappears, it does not re-emerge as another symptom.

Recurrent or Persistent Wheeze.

Wheezing is a relatively frequent and particularly troublesome manifestation of obstructive lower respiratory tract disease in children. The site of obstruction may be anywhere from the intrathoracic trachea to the small bronchi or large bronchioles, but the sound is generated by turbulence in larger airways that collapse with forced expiration. Children younger than 2–3 yr of age are especially prone to wheezing, because bronchospasm, mucosal edema, and accumulation of excessive secretions have a relatively greater obstructive effect on their smaller airways. In addition, the compliant airways in young children collapse more readily with active expiration. Isolated episodes of acute wheezing, such as may occur with bronchiolitis, are not uncommon, but wheezing that recurs or persists for longer than 4 wk suggests other diagnoses (see Table 379–2). Most recurrent or persistent wheezing in children is the result of reactive airways disease. Nonspecific environmental factors such as cigarette smoke may be important contributors.

Frequently recurring or persistent wheezing starting at or soon after birth suggests a variety of other diagnoses, including congenital structural abnormalities involving the lower respiratory tract or tracheobronchomalacia. Wheezing that attends cystic fibrosis is most common in the first year of life. Sudden onset of severe wheezing in a previously healthy child should suggest foreign body aspiration.

Repeated examination may be required to verify a history of wheezing in a child with episodic symptoms and should be directed toward assessing air movement, ventilatory adequacy, and evidence of chronic lung disease, such as fixed overinflation of the chest, growth failure, and digital clubbing. Clubbing suggests chronic lung infection and is rarely prominent in uncomplicated asthma. Tracheal deviation from foreign body aspiration should be sought. It is essential to rule out wheezing secondary to congestive heart failure. Allergic rhinitis, urticaria, eczema, or evidence of ichthyosis vulgaris suggests asthma or asthmatic bronchitis. The nose should be examined for polyps, which may exist with allergic conditions or cystic fibrosis.

Sputum eosinophilia and elevated serum IgE levels suggest allergic reactions. An FEV_1 increase of 15% in response to bronchodilators is confirmatory of reactive airways. Specific microbiologic studies, special imaging studies of the airways and cardiovascular structures, diagnostic studies for cystic fibrosis, and bronchoscopy should be considered if the response is unsatisfactory.

Frequently Recurring or Persistent Stridor.

Stridor, a harsh, medium-pitched, inspiratory sound associated with obstruction of the laryngeal area or the extrathoracic trachea, is often accompanied by a croupy cough and hoarse voice. Stridor is most commonly observed in children with croup; foreign bodies and trauma may also cause acute stridor. However, a small number of children acquire recurrent stridor or have persistent stridor from the first days or weeks of life (Box 370–3). Most congenital anomalies of large airways that produce stridor become symptomatic soon after birth. Increase of stridor when a child is supine suggests laryngomalacia or tracheomalacia. An accompanying history of hoarseness or aphonia suggests involvement of the vocal cords.

Physical examination for recurrent or persistent stridor is usually unrewarding, although changes in its severity and intensity due to changes of body position should be assessed. Anteroposterior and lateral roentgenograms, contrast esophagography, fluoroscopy, CT, and MRI are potentially useful diagnostic tools. In most cases, direct observation is necessary for diagnosis. Undistorted views of the larynx are best obtained with fiberoptic laryngoscopy.

Recurrent and Persistent Lung Infiltrates.

Radiographic lung infiltrates resulting from acute pneumonia usually resolve within 1–3 wk, but a substantial number of children, particularly infants, fail to completely clear infiltrates within a 4-wk period. They may be febrile or afebrile and may display a wide range of respiratory symptoms and signs. Persistent or recurring infiltrates present a diagnostic challenge (Box 370–4).

Symptoms associated with chronic lung infiltrates during the first several weeks of life (but not related to neonatal respiratory distress syndrome) suggest infection acquired in utero or during descent through the birth canal. Early appearance of

chronic infiltrates may also be associated with cystic fibrosis or congenital

anomalies, which result in aspiration or airway obstruction. A history of recurrent infiltrates, wheezing, and cough may reflect asthma, even in the first year of life.

One uncommon but characteristic syndrome appearing in the first year of life with recurrent lung infiltrates is pulmonary hemosiderosis related to cow's milk hypersensitivity. Children with a history of bronchopulmonary dysplasia frequently have episodes of respiratory distress attended by wheezing and new lung infiltrates. Recurrent pneumonia in a child with frequent otitis media, nasopharyngitis, adenitis, or dermatologic manifestations suggests an immunodeficiency state, complement deficiency, or phagocytic defect. Particular attention must be directed to the possibility that the infiltrates represent lymphocytic interstitial pneumonitis or opportunistic infection associated with human immunodeficiency virus infection. A history of paroxysmal coughing in an infant suggests pertussis syndrome or cystic fibrosis. Persistent infiltrates, especially with loss of volume, in a toddler should

suggest foreign body aspiration.

Overinflation and infiltrates suggest cystic fibrosis or chronic asthma. A “silent chest” with infiltrates should arouse suspicion of alveolar proteinosis, *Pneumocystis carinii* infection, desquamative interstitial pneumonitis, or tumors. Growth should be carefully assessed to determine whether the lung process has had systemic effects, indicating substantial severity and chronicity as in cystic fibrosis or alveolar proteinosis. Cataracts, retinopathy, or microcephaly suggest in utero infection. Chronic rhinorrhea may be associated with atopic disease, cow's milk intolerance, cystic fibrosis, or congenital syphilis. The absence of tonsils and cervical lymph nodes suggests an immunodeficiency state.

Diagnostic studies should be performed selectively, based on information obtained from history and physical examination and on a thorough understanding of the conditions listed in Box 370–4 . Cytologic evaluation of sputum, if available, may be helpful. Chest CT often provides more precise anatomic detail concerning the infiltrate. Bronchoscopy is indicated for detecting

foreign bodies, congenital or acquired anomalies of the tracheobronchial tract, and obstruction by endobronchial or extrinsic masses. Bronchoscopy provides access to secretions that can be studied cytologically and microbiologically. Alveolar lavage fluid is diagnostic for alveolar proteinosis and persistent pulmonary hemosiderosis and may suggest aspiration syndromes. If all appropriate studies have been completed and the condition remains undiagnosed, lung biopsy may yield a definitive diagnosis.

Optimal medical or surgical treatment of chronic lung infiltrates frequently depends on a specific diagnosis, but chronic conditions may be self-limiting (e.g., severe and prolonged viral

infections in infants); in these cases, symptomatic therapy may maintain adequate lung function until spontaneous improvement occurs. Helpful measures include inhalation and physical therapy for excessive secretions, antibiotics for bacterial infections, supplementary oxygen for hypoxemia, and maintenance of adequate nutrition. Because the lung of a young child has remarkable recuperative potential, normal lung function may ultimately be achieved with treatment despite the severity of pulmonary insult occurring during infancy or early childhood.

Chapter 371 - Acute Inflammatory Upper Airway Obstruction

Genie E. Roosevelt

General Considerations.

Acute inflammation of the upper airway is of great importance in infants and small children. Airway resistance is inversely proportional to the fourth power of the radius; therefore, minor reductions in cross-sectional area due to mucosal edema or other inflammatory processes cause an exponential increase in airway resistance and a significant increase in the work of breathing. The larynx is composed of four major cartilages (epiglottic, arytenoid, thyroid, and cricoid cartilages, from superior to inferior, respectively) and the soft tissues that surround them. The cricoid cartilage encircles the airway just below the vocal cords and defines the narrowest portion of the upper airway in children younger than 10 yr of age.

Inflammation involving the vocal cords and structures inferior to the cords is called laryngitis, laryngotracheitis, or laryngotracheobronchitis, and inflammation of the structures superior to the cords (i.e., arytenoids, aryepiglottic folds ["false cords"], epiglottis) is called supraglottitis. The term *croup* refers to a heterogeneous group of mainly acute and infectious processes that are characterized by a barklike or brassy cough and may be associated with hoarseness, inspiratory stridor, and respiratory distress. Stridor is a harsh, high-pitched respiratory sound, usually inspiratory but may be biphasic, produced by turbulent airflow; it is not a diagnosis but a sign of upper airway obstruction (also see Chapter 370). Croup usually affects to some degree the larynx, trachea, and bronchi. When the involvement of the larynx is sufficient to produce symptoms, they dominate the clinical picture over the tracheal and bronchial signs. Traditionally, a distinction has been made between spasmodic or recurrent croup and laryngotracheobronchitis. Some clinicians believe that spasmodic croup may have an allergic component and improves rapidly without treatment whereas laryngotracheobronchitis is always associated with a viral infection of the respiratory tract. Others believe that the signs and symptoms are similar enough to consider them within the spectrum of a single disease.

371.1 Infectious Upper Airway Obstruction

Etiology and Epidemiology.

Viral agents account for most acute infectious upper airway obstructions. The exceptions are diphtheria, bacterial tracheitis, and epiglottitis. The parainfluenza viruses (types 1, 2, and 3) account for approximately 75% of cases; other viruses associated with this disease include influenza A and B, adenovirus, respiratory syncytial virus (RSV), and measles. Influenza A has been associated with severe laryngotracheobronchitis. *Mycoplasma pneumoniae* rarely has been isolated from children with croup and causes mild disease. Most patients with croup are between the ages of 3 mo and 5 yr, with the peak in the second year of life. The incidence of croup is higher in males, and it occurs most commonly during the winter but may occur throughout the year. Recurrences are frequent from 3–6 yr of age and decrease with growth of the airway. Approximately 15% of patients have a strong family history of croup.

In the past, *Haemophilus influenzae* type b was the most commonly identified etiology of acute epiglottitis. Since the widespread use of the HiB vaccine in the United States, invasive disease due to *H. influenzae* type b in pediatric patients has been reduced by 80–90%. Therefore, other agents, such as *Streptococcus pyogenes*, *S. pneumoniae*, and *Staphylococcus aureus*, now represent a larger proportion of pediatric cases of epiglottitis. In the pre-vaccine era, the typical patient was 2–4 yr of age, although cases were seen in the first year of life and in patients as old as 7 yr of age. Currently, the typical patient with epiglottitis is an adult with a sore throat, although cases still do occur in underimmunized children.

Clinical Manifestations

CROUP (LARYNGOTRACHEOBRONCHITIS).

Primarily, viruses cause croup, the most common form of acute upper respiratory obstruction. The term *laryngotracheobronchitis* refers to this viral infection of the glottic and subglottic regions. However, some clinicians use the term *laryngotracheitis* for the most common and most typical form of croup and reserve the term laryngotracheobronchitis for the more severe form that is considered an extension of laryngotracheitis associated with bacterial superinfection that occurs 5 to 7 days into the clinical course.

Most patients have an upper respiratory tract infection with some combination of rhinorrhea, pharyngitis, mild cough, and low-grade fever for 1 to 3 days before the signs and symptoms of upper airway obstruction become apparent. The child then develops the characteristic “barking” cough, hoarseness, and inspiratory stridor. The low-grade fever may persist, although temperatures may reach 39–40°C (102.2–104°F); some children are afebrile. Symptoms are characteristically worse at night and often recur with decreasing intensity for several days and resolve completely within a week. Agitation and crying greatly aggravate the symptoms and signs. The child may prefer to sit up in bed or be held upright. Older children usually are not seriously ill. Other family members may have mild respiratory illnesses. Most patients with croup progress only as far as stridor and slight dyspnea before they start to recover.

Physical examination may reveal a hoarse voice, coryza, normal to moderately inflamed pharynx, and a slightly increased respiratory rate. Patients may vary substantially in their degree of respiratory distress. Rarely, the upper airway obstruction progresses and is accompanied by an increasing respiratory rate; nasal flaring; suprasternal, infrasternal, and intercostal retractions; and continuous stridor. Croup is a disease of the upper airway, and alveolar gas exchange is usually normal. Hypoxia and low oxygen saturation are seen only when complete airway obstruction is imminent. The child who is hypoxic, cyanotic, pale, or obtunded needs immediate airway management. Occasionally, the pattern of severe laryngotracheobronchitis may be difficult to differentiate from epiglottitis despite the usually more acute onset and rapid course of the latter.

Croup is a clinical diagnosis and does not require a radiograph of the neck. Radiographs of the neck may show the typical subglottic narrowing or “steeple sign” of croup on the posteroanterior view (Fig. 371–1). However, the “steeple sign” may be absent in patients with croup, may be present in patients without croup as a normal variant, and may be present in patients with epiglottitis. In addition, the radiographs do not correlate well with disease severity. Radiographs should be considered only after airway stabilization in children who have an atypical presentation or clinical course. Radiographs may be helpful in distinguishing between severe laryngotracheobronchitis and epiglottitis, but airway management should always take priority.

ACUTE EPIGLOTTITIS (SUPRAGLOTTITIS).

This dramatic, potentially lethal condition is characterized by an acute fulminating course of high fever, sore throat, dyspnea, and rapidly progressing respiratory obstruction. The degree of respiratory distress at presentation is variable. The initial lack of respiratory distress may deceive the unwary clinician, although respiratory distress may be the first manifestation. Often the otherwise healthy child suddenly develops a sore throat and fever. Within a matter of hours, the patient appears toxic, swallowing is difficult, and breathing is labored. Drooling is usually present and the neck is hyperextended in an attempt to maintain the airway. The child may assume the tripod position sitting upright and leaning forward with the chin up and mouth open while bracing on the arms. A brief period of air hunger with restlessness may be followed by rapidly increasing

Figure 371.1-1 Radiograph of an airway of a patient with croup, showing typical subglottic narrowing (“steeple sign”).

cyanosis and coma. Stridor is a late finding and suggests near-complete airway obstruction. Complete obstruction of the airway and death may ensue unless adequate treatment is provided. The barking cough typical of croup is rare. Usually no other family members are ill with acute respiratory symptoms.

The *diagnosis* requires visualization of a large, “cherry-red” swollen epiglottis by laryngoscopy. Occasionally, the other supraglottic structures, especially the

aryepiglottic folds, may be more involved than the epiglottis itself. In a patient in whom the diagnosis is certain or probable based on clinical grounds, laryngoscopy should be performed expeditiously in a controlled environment such as an operating room or intensive care unit depending on the institution. Anxiety provoking interventions such as phlebotomy, intravenous line placement, placing the child supine, or direct inspection of the oral cavity should be avoided until the airway is secure. If epiglottitis is thought to be possible, although not probable, in a patient with acute upper airway obstruction, the patient may undergo lateral radiographs of the upper airway first. Classic radiographs of a child who has epiglottitis show the “thumb sign” (Fig. 371–2). If the concern for epiglottitis still exists after the radiographs, visualization should be performed as described previously. Regardless, a physician skilled in airway management and use of intubation equipment should accompany patients with suspected epiglottitis at all times. Occasionally, an older cooperative child may voluntarily open the mouth wide enough for a direct view of the inflamed epiglottis.

Establishing an airway by nasotracheal intubation or, less often, by tracheostomy is indicated in patients with epiglottitis, regardless of the degree of apparent respiratory distress, because as many as 6% of children with epiglottitis without an artificial airway die, compared with less than 1% of those with an artificial airway. No clinical features have been recognized that predict mortality. Pulmonary edema may be associated with acute airway obstruction. The duration of intubation depends on the clinical course of the patient and the duration of epiglottic swelling, as determined by frequent examination using direct laryngoscopy or flexible fiberoptic laryngoscopy. In general, children with acute epiglottitis are intubated for 2–3 days, because the response to antibiotics is usually rapid (see later). Most patients have concomitant bacteremia; occasionally, other infections may be present, such as pneumonia, cervical adenopathy, or otitis media. Meningitis, arthritis, and other invasive infections with *H. influenzae* type b are rarely found in conjunction with epiglottitis.

Figure 371.1-2 Epiglottitis. Lateral roentgenogram of the upper airway reveals the swollen epiglottis (“thumb sign”).

ACUTE INFECTIOUS LARYNGITIS.

Laryngitis is a common illness; viruses cause most cases; diphtheria is an exception but is extremely rare in developed countries. The onset is usually characterized by an upper respiratory tract infection during which sore throat, cough, and hoarseness appear. The illness is generally mild; respiratory distress is unusual except in the young infant. Hoarseness and loss of voice may be out of proportion to systemic signs and symptoms. The physical examination is usually not remarkable except for evidence of pharyngeal inflammation. Inflammatory edema of the vocal cords and subglottic tissue may be demonstrated laryngoscopically. The principal site of obstruction is usually the subglottic area.

SPASMODIC CROUP.

Spasmodic croup occurs most often in children 1–3 yr of age and is clinically similar to acute laryngotracheobronchitis, except that the history of a viral prodrome and fever in the patient and family are frequently absent. The cause is viral in some cases, but allergic and psychological factors may be important in others. Laryngoscopy reveals pale, watery edema with preservation of the epithelium (unlike the erythematous edema and destruction of the epithelium of acute infectious laryngotracheobronchitis).

Occurring most frequently in the evening or nighttime, spasmodic croup begins with a sudden onset that may be preceded by mild to moderate coryza and hoarseness. The child awakens with a characteristic barking, metallic cough, noisy inspiration, and respiratory distress and appears anxious and frightened. The patient is usually afebrile. Usually, the severity of the symptoms diminishes within several hours and, the following day, the patient often appears well except for slight hoarseness and cough. Similar, but usually less severe, attacks without extreme respiratory distress may occur for another night or two. Such episodes often recur several times. Spasmodic croup may represent more of an allergic reaction to viral antigens than direct infection, although the pathogenesis is unknown.

Differential Diagnosis.

These four syndromes must be differentiated from one another and from a variety of other entities that may present as upper airway obstruction. *Bacterial tracheitis* is the most important differential diagnostic consideration. **Diphtheritic croup** is extremely rare in North America, although a major epidemic of diphtheria occurred in countries of the former Soviet Union beginning in 1990 from the lack of routine immunization of adults (see Chapter 172). Early symptoms include malaise, sore throat, anorexia, and low-grade fever. Within 2–3 days, pharyngeal examination reveals the typical gray-white membrane, which may vary in size from covering a small patch on the tonsils to covering most of the soft palate. The membrane is adherent to the tissue, and forcible attempts to remove it cause bleeding. The course is usually insidious, but respiratory obstruction may occur suddenly. *Measles croup* almost always coincides with the full manifestations of systemic disease and the course may be fulminant (see Chapter 225).

Sudden onset of respiratory obstruction may be caused by *aspiration of a foreign body* (see Chapter 373). The child is usually 6 mo to 2 yr of age. Choking and coughing occur suddenly, usually without prodromal signs of infection, although children with a viral infection can also aspirate a foreign body. A *retropharyngeal or peritonsillar abscess* may mimic respiratory obstruction (see Chapter 367). Radiographs of the upper airway and chest are essential in evaluating these possibilities. Other possible causes of upper airway obstruction include *extrinsic compression* of the airway (e.g., laryngeal web, vascular ring) and *intraluminal obstruction* from masses (e.g., laryngeal papilloma, subglottic hemangioma).

Upper airway obstruction is occasionally associated with angioedema of the subglottic areas as part of anaphylaxis and generalized allergic reactions, edema after endotracheal intubation for general anesthesia or respiratory failure, *hypocalcemic tetany*, *infectious mononucleosis*, trauma, and tumors or malformations of the larynx. A croupy cough may be an early sign of asthma. Vocal cord dysfunction can also occur. Epiglottitis, with the characteristic manifestations of

drooling or dysphagia and stridor, can also result from the accidental ingestion of very hot liquid.

Complications.

Complications occur in approximately 15% of patients with viral croup. The most common is extension of the infectious process to involve other regions of the respiratory tract, such as the middle ear, the terminal bronchioles, or the pulmonary parenchyma. Bacterial tracheitis may be a complication of viral croup rather than a distinct disease. Pneumonia, cervical lymphadenitis, otitis media, or, rarely, meningitis or septic arthritis may occur during the course of epiglottitis. Mediastinal emphysema and pneumothorax are the most common complications of tracheotomy.

Treatment.

The mainstay of treatment for children with **croup** is airway management. Treatment of the respiratory distress should take priority over any testing. However, most children with either acute spasmodic croup or infectious croup can be managed at home safely. Mist was first used in the 19th century when physicians anecdotally witnessed an improvement in the symptoms of croup with the steam from teapots and hot tubs. Given the risk of burns and the observation that cold night air is also beneficial led to the use of *cool mist*. The proposed mechanisms to explain the beneficial effect of cool mist are that it (1) moistens airway secretions to facilitate clearance, (2) soothes inflamed mucosa, and (3) provides comfort and reassurance to the child, lessening any anxiety. Two studies tested the efficacy of moist air in patients with croup. Neither study showed a beneficial effect, although the sample sizes were small. In a study comparing nebulized saline placebo to racemic epinephrine, croup scores significantly improved after the administration of the placebo, although there was no control group. Improvement may be explained by spontaneous recovery with time. Current recommendations are to provide cool mist through a tube held in front of the patient by the parent. Children with both wheezing and croup concomitantly may experience worsening of their bronchospasm with cool mist.

The marked decrease in the need for tracheotomies in **croup** has been attributed to the use of *nebulized epinephrine*. Although initially used with intermittent positive pressure ventilation, subsequent studies showed effectiveness with simple nebulization. The mechanism of action is believed to be constriction of the precapillary arterioles through the a-adrenergic receptors causing fluid resorption from the interstitial space and a decrease in the laryngeal mucosal edema. Traditionally, racemic epinephrine, a 1:1 mixture of the *d*- and *l*-isomers of epinephrine, has been administered. A dose of 0.25 to 0.75?mL of 2.25% racemic epinephrine in 3?mL of normal saline can be used as often as every 20?min. Racemic epinephrine was initially chosen over the more active and more readily available *l*-epinephrine to minimize anticipated cardiovascular side effects such as tachycardia and hypertension. However, there is evidence that *l*-epinephrine (5?mL of 1:1,000 solution) is equally effective as racemic epinephrine and does not carry the risk of additional adverse effects. This information is both practical and important, because racemic epinephrine is not available outside the United States.

The indications for the administration of nebulized epinephrine include moderate to severe stridor at rest, the need for intubation, respiratory distress, hypoxia, and when stridor does not respond to cool mist. The duration of activity of racemic epinephrine is less than 2?hr. The symptoms of croup may reappear, but racemic epinephrine does not cause rebound worsening of the obstruction. Therefore, observation is mandated. Patients may be safely discharged home after a 2–3?hr period of observation provided they have no stridor at rest, normal air entry, normal color, and normal level of consciousness and have received

steroids (see later). Nebulized epinephrine should still be used cautiously in patients with tachycardia, heart conditions such as tetralogy of Fallot, or ventricular outlet obstruction because of possible side effects.

After several decades of debate about the effectiveness of corticosteroids in viral croup, there is now clear evidence of their benefit. *Corticosteroids* decrease the edema in the laryngeal mucosa through their anti-inflammatory action. Studies have demonstrated that steroids are beneficial, as measured by reduced hospitalization, shorter duration of hospitalization, and reduced need for subsequent interventions such as epinephrine administration. Most studies that demonstrated the efficacy of dexamethasone used a single dose of 0.6?mg/kg; however, there is some evidence that a dose as low as 0.15?mg/kg may be just as effective. Intramuscular dexamethasone and nebulized budesonide have an equivalent clinical effect, and oral dosing of dexamethasone is as effective as intramuscular administration. The only adverse effect described in the treatment of croup with corticosteroids was the development of *Candida albicans* laryngotracheitis in a patient who received dexamethasone, 1?mg/kg/24?hr, for 8 days. Corticosteroids should not be administered to children with varicella or tuberculosis (unless the patient is receiving appropriate anti-tuberculosis therapy) because they worsen the clinical course.

Antibiotics are not indicated in croup. Preliminary studies with a helium-oxygen mixture (Heliox) have shown similar clinical improvements in children with croup when compared with responses in children given racemic epinephrine.

Children with croup should be *hospitalized* for any of the following: progressive stridor, severe stridor at rest, respiratory distress, hypoxia, cyanosis, depressed mental status, or the need for reliable observation.

Epiglottitis is a medical emergency and warrants immediate treatment with an *artificial airway* placed under controlled conditions, either in an operating room or intensive care unit. All patients should receive *oxygen* en route unless the mask causes excessive agitation. Racemic epinephrine and corticosteroids are ineffective. Cultures of blood, epiglottic surface, and, in selected cases, cerebrospinal fluid, should be collected at the time of airway stabilization. *Ceftriaxone, cefotaxime*, or a combination of ampicillin and sulbactam should be given parenterally pending culture and susceptibility reports because from 10–40% of *H. influenzae* type b cases are resistant to ampicillin. After insertion of the artificial airway, the patient should improve immediately, and respiratory distress and cyanosis should disappear. Epiglottitis resolves after a few days of antibiotics, and the patient may be extubated; antibiotics should be continued for 7–10 days. Chemoprophylaxis is not

recommended for household contacts of patients with invasive *H. influenzae* type b infections unless there is a child younger than 48 mo in the home who has not completed the HiB immunization series. Rifampin prophylaxis (20?mg/kg orally once a day for 4 days; maximum dose, 600?mg) should be given to all household members if there is one contact younger than 48 mo of age who is incompletely immunized or if there is an immunocompromised child in the household.

Acute laryngeal swelling *on an allergic basis* responds to epinephrine (1:1,000 dilution in dosage of 0.01?mL/kg to a maximum of 0.5?mL/dose) administered subcutaneously or racemic epinephrine (dose of 0.25–0.75?mL of 2.25% racemic epinephrine in 3?mL of normal saline). Corticosteroids are frequently required (2–4?mg/kg/24?hr of prednisone. After recovery, the patient and parents should be discharged with a preloaded syringe of epinephrine to be used in emergencies. Reactive mucosal swelling, severe stridor, and respiratory distress unresponsive to mist therapy may follow *endotracheal intubation* for general anesthesia in children. Racemic epinephrine and corticosteroids are helpful.

TRACHEOTOMY AND ENDOTRACHEAL INTUBATION

(see Chapter 57.1). With the introduction of routine nasotracheal intubation or tracheotomy for epiglottitis, the mortality rate has dropped to almost zero. Both procedures should always be performed in an operating room or intensive care unit if time permits; prior intubation and general anesthesia greatly facilitate performing a tracheotomy without complications. The use of a nasotracheal tube that is 0.5–1.0?mm smaller than estimated by age is recommended to facilitate intubation and reduce long-term sequelae. The choice of procedure should be based on the local expertise and experience with the procedure and the postoperative care involved with each.

Endotracheal intubation or tracheotomy is required for all patients with epiglottitis, but for patients with laryngotracheobronchitis, spasmodic croup, or laryngitis, it is rarely required. Severe forms of laryngotracheobronchitis that require tracheotomy in a high proportion of patients have been reported during severe measles and influenza A virus epidemics. Assessing the need for these procedures requires experience and judgment because they should not be delayed until cyanosis and extreme restlessness have developed (see Chapter 55 , Chapter 57.3 , and Chapter 58).

The endotracheal tube or tracheostomy must remain in place until edema and spasm have subsided and the patient is able to handle secretions satisfactorily. It should be removed as soon as possible, usually within a few days. Adequate resolution of epiglottic inflammation that has been accurately confirmed by fiberoptic laryngoscopy, permitting much more rapid extubation, often occurs within 24?hr. Racemic epinephrine and dexamethasone (0.5?mg/kg/dose every 6?hr as needed) may be useful in the treatment of croup associated with extubation.

Prognosis.

In general, the length of hospitalization and the mortality rate for cases of acute infectious upper airway obstruction increase as the infection extends to involve a greater portion of the respiratory tract, except in epiglottitis, in which the localized infection itself may prove to be fatal. Most deaths from croup are caused by a laryngeal obstruction or by the complications of tracheotomy. Untreated epiglottitis has a mortality rate of 6% in some series, but if the diagnosis is made and appropriate treatment is initiated before the patient is moribund, the prognosis is excellent. The outcome of acute laryngotracheobronchitis, laryngitis, and spasmodic croup is also excellent. As a group, children who need to be hospitalized for croup have somewhat increased bronchial reactivity compared with normal children when tested several years later but the significance is uncertain.

371.2 Bacterial Tracheitis

Bacterial tracheitis, an acute bacterial infection of the upper airway, does not involve the epiglottitis but, like epiglottitis and croup, is capable of causing life-threatening airway obstruction. *Staphylococcus aureus* is the most commonly isolated pathogen. *Moraxella catarrhalis*, nontypable *H. influenzae*, and anaerobic organisms have also been implicated. Most patients are younger than 3 yr of age, although older children may be affected. There are no clear sex differences in incidence or severity. Bacterial tracheitis often follows a viral respiratory infection (especially laryngotracheitis) so it may be considered a bacterial complication of a viral disease, rather than a primary bacterial illness. This life-threatening entity is now more common than epiglottitis.

Clinical Manifestations.

Typically, the child has a brassy cough, apparently as part of a viral laryngotracheobronchitis. High fever and "toxicity" with respiratory distress may occur immediately or after a few days of apparent improvement. The patient with bacterial tracheitis can lie flat, does not drool, and does not have the dysphagia associated with epiglottitis. The usual treatment for croup (e.g., mist, racemic epinephrine) is ineffective. Intubation or tracheostomy may be necessary. The major pathologic feature appears to be mucosal swelling at the level of the cricoid cartilage, complicated by copious thick, purulent secretions, sometimes causing pseudomembranes. Suctioning these secretions, although occasionally affording temporary relief, usually does not sufficiently obviate the need for an artificial airway.

Diagnosis.

The diagnosis is based on evidence of bacterial upper airway disease, which includes high fever, purulent airway secretions, and an absence of the classic findings of epiglottitis.

Treatment.

Appropriate antimicrobial therapy, which usually includes antistaphylococcal agents, should be instituted in any patient whose course suggests bacterial tracheitis. When bacterial tracheitis is diagnosed by direct laryngoscopy or is strongly suspected on clinical grounds, an artificial airway is indicated. Supplemental oxygen may be necessary.

Complications.

Chest radiographs often show patchy infiltrates and may show focal densities. Subglottic narrowing and a rough and ragged tracheal air column can often be demonstrated radiographically. If airway management is not optimal, cardiorespiratory arrest can occur. Toxic shock syndrome has been associated with tracheitis (see Chapter 166.2).

Prognosis.

The prognosis for most patients is excellent. Patients usually become afebrile within 2–3 days of the institution of appropriate antimicrobial therapy, but prolonged hospitalization may be necessary. With a decrease in mucosal edema and purulent secretions, extubation can be accomplished safely, and the patient should be observed carefully while antibiotics and oxygen therapy are continued.

Chapter 372 - Congenital Anomalies of the Larynx

Lauren D. Holinger

Because the larynx functions as a breathing passage, a valve to protect the lungs, and the primary organ of communication, symptoms of laryngeal anomalies are those of airway obstruction, difficulty feeding, and abnormalities of phonation.

With airway obstruction, the severity of the obstructing lesion determines the necessity for diagnostic procedures and surgical intervention. Obstructive symptoms vary from mild stridor to severe obstruction, with episodes of apnea, cyanosis, suprasternal (tracheal tugging) and subcostal retractions, dyspnea, and tachypnea. Chronic obstruction may cause failure to thrive.

372.1 Laryngomalacia

Laryngomalacia is the most common congenital laryngeal anomaly and the most frequent cause of stridor in infants and children. Of congenital laryngeal anomalies in children with stridor, 60% are caused by laryngomalacia. Typically, stridor is inspiratory, low pitched, and exacerbated by any exertion (i.e., crying, agitation, feeding). Stridor results from the collapse of supraglottic structures inward during inspiration. Symptoms usually appear within the first 2 wk of life and increase in severity for up to 6 mo, although gradual improvement may begin at any time. Laryngopharyngeal reflux is commonly associated with laryngomalacia.

The diagnosis is confirmed by flexible laryngoscopy in the office. When the work of breathing is moderate to severe, airway films and chest radiographs are indicated. With associated dysphagia, a contrast swallow study and esophagogram may be indicated. Because 15–60% of infants with laryngomalacia have synchronous airway anomalies, complete bronchoscopy is undertaken for patients with moderate to severe obstruction.

Expectant observation is suitable for most infants because most symptoms resolve spontaneously. Laryngopharyngeal reflux is managed aggressively. For those few patients who have such severe obstruction that surgical intervention is unavoidable—patients with apparent life-threatening events, cor pulmonale, cyanosis, failure to thrive—endoscopic supraglottoplasty can be used to avoid

tracheotomy.

372.2 Congenital Subglottic Stenosis

Congenital subglottic stenosis is the second most common cause of stridor. Stridor is biphasic or primarily inspiratory. Recurrent or persistent croup is typical. First symptoms often occur with a respiratory tract infection as edema and thickened secretions of a common cold narrow an already compromised airway.

1410

The diagnosis made by airway radiographs is confirmed by direct laryngoscopy. As with all cases of upper airway obstruction, tracheostomy is avoided when possible. Dilation and endoscopic laser surgery are rarely effective because most congenital stenoses are cartilaginous. Anterior laryngotracheal decompression (cricoid split) or laryngotracheal reconstruction with cartilage grafting is usually effective in avoiding tracheostomy (also see Chapter 374).

372.3 Vocal Cord Paralysis

Vocal cord paralysis is the third most common congenital laryngeal anomaly producing stridor in infants and children. Congenital central lesions such as myelomeningocele, Arnold-Chiari malformation, and hydrocephalus are often associated. Paralysis may occur as a result of surgical correction of congenital cardiac anomalies or tracheoesophageal fistula.

Bilateral vocal cord paralysis typically produces airway obstruction manifested by high-pitched inspiratory stridor: a phonatory sound or inspiratory cry. Unilateral paralysis causes aspiration, coughing, and choking. The cry is weak and breathy, but stridor and other symptoms of airway obstruction are less common.

The diagnosis of vocal cord paralysis is made by awake flexible laryngoscopy. A thorough investigation for the underlying cause is indicated. Because of the association with other congenital lesions, evaluation includes neurology and cardiology consultations as well as diagnostic endoscopy of the larynx, trachea, and bronchi.

Vocal cord paralysis in infants usually resolves spontaneously within 6–12 mo. Bilateral paralysis may require temporary tracheotomy. For unilateral vocal cord paralysis with aspiration, the paralyzed vocal cord is injected laterally so that it touches the now paralyzed cord medially, reducing aspiration and related complications.

372.4 Congenital Laryngeal Webs and Atresia

Most congenital laryngeal webs are glottic with subglottic extension and associated subglottic stenosis. The cry may be high pitched. Airway obstruction is not always present and may be related to the subglottic stenosis. Thick webs may be suspected in lateral radiographs of the airway. Diagnosis is made by direct laryngoscopy. Treatment may require only incision or dilation. Webs with associated subglottic stenosis are likely to require cartilage augmentation of the cricoid (laryngotracheal reconstruction).

Laryngeal atresia occurs as a complete glottic web and commonly is associated with tracheal agenesis and tracheoesophageal fistula. It is not compatible with long-term survival.

372.5 Congenital Subglottic Hemangioma

See Chapter 377.3 .

372.6 Laryngoceles and Saccular Cysts

A laryngocele is an abnormal air-filled dilation of the laryngeal saccule. It communicates with the laryngeal lumen and, when intermittently filled with air, causes hoarseness and dyspnea. A saccular cyst (congenital cyst of the larynx) is distinguished from the laryngocele in that its lumen is isolated from the interior of the larynx and it contains mucus, not air. A saccular cyst may be visible on radiography, but the diagnosis is made by laryngoscopy. Needle aspiration of the cyst confirms the diagnosis but rarely provides a cure. Endoscopic CO_2 laser excision may suffice, but external excision is often necessary.

372.7 Posterior Laryngeal Cleft and Laryngotracheoesophageal Cleft

The rare posterior laryngeal cleft (PLC) is characterized by deficiency in the midline of the posterior larynx. In severe cases the cleft extends inferiorly into the cervical or thoracic trachea so there is no separation between the trachea and esophagus—laryngotracheoesophageal cleft (LTEC). Laryngeal clefts may occur in families and are likely to be associated with tracheal agenesis, tracheoesophageal fistula, and multiple congenital anomalies, as with G syndrome, Opitz-Frias syndrome, and Pallister-Hall syndrome.

Initial symptoms are those of aspiration and respiratory difficulties. The cry may be weak or absent. An esophagogram is done with extreme caution. Confirmation of the diagnosis is made by direct laryngoscopy and bronchoscopy. Stabilization of the airway is the first priority. Gastroesophageal reflux must be controlled, and a careful assessment for other congenital anomalies should be undertaken.

Chapter 373 - Foreign Bodies of the Airway

Lauren D. Holinger

Epidemiology and Etiology.

Although there has been a decrease in childhood deaths from asphyxiation by ingested objects, the incidence of foreign body aspiration has not changed significantly and is unlikely to do so as long as children continue to use their mouths to explore their surroundings. Most victims of foreign body aspiration are older infants and toddlers. Children younger than 3 yr of age account for 73% of cases. One third of aspirated objects are nuts, particularly peanuts. Fragments of raw carrot, apple, dried beans, popcorn, and sunflower or watermelon seeds are also common.

Clinical Manifestations.

A positive history must never be ignored. A negative history may be misleading. Choking or coughing episodes accompanied by wheezing are highly suggestive of an airway foreign body. Because nuts are the most common bronchial foreign body, the physician specifically questions the toddler's parents about nuts. If there is any history of eating nuts, bronchoscopy is carried out promptly.

The most serious complication of foreign body aspiration is complete obstruction of the airway. Globular food objects such

as hot dogs, grapes, nuts, and candies are the most frequent offenders. Hot dogs are rarely seen as airway foreign bodies because toddlers who choke on hot dogs asphyxiate on the spot unless treated immediately. Complete airway obstruction is recognized in the conscious child as sudden respiratory distress followed by inability to speak or cough.

Three stages of symptoms result from aspiration of an object into the airway:

1. Initial Event: Violent paroxysms of coughing, choking, gagging, and possibly airway obstruction occur immediately when the foreign body is aspirated.
2. Asymptomatic Interval: The foreign body becomes lodged, reflexes fatigue, and the immediate irritating symptoms subside. This stage is most treacherous and accounts for a large percentage of delayed diagnoses and overlooked foreign bodies. It is during this second stage that the physician may minimize the possibility of a foreign body accident, being reassured by the absence of symptoms that no foreign body is present.
3. Complications: In this third stage, obstruction, erosion, or infection develops to again direct attention to the presence of a foreign body. Complications include fever, cough, hemoptysis, pneumonia, and atelectasis.

Treatment.

The treatment of choice for airway foreign bodies is prompt endoscopic removal with rigid instruments. Bronchoscopy is deferred only until preoperative studies have been obtained and the patient has been prepared by adequate hydration and emptying of the stomach. Airway foreign bodies are usually removed the same day the diagnosis is first considered (also see Chapter 57.1).

373.1 Laryngeal Foreign Bodies

Complete obstruction asphyxiates the child unless promptly relieved with the Heimlich maneuver (see Chapter 57.1).

Figure 373.1-1 *A*, Normal inspiratory chest radiograph in a toddler with a peanut fragment in the left main bronchus. *B*, Expiratory radiograph of the same child showing the classic obstructive emphysema (air trapping) on the involved (left) side. Air leaves the normal right side, allowing the lung to deflate. The medium shifts toward the unobstructed side.

Objects that are partially obstructive are usually flat and thin. They lodge between the vocal cords in the saggital plane, causing symptoms of croup, hoarseness, cough, stridor, and dyspnea.

373.2 Tracheal Foreign Bodies

Choking and aspiration occurs in 90% of patients with tracheal foreign bodies, stridor in 60%, and wheezing in 50%. Posteroanterior and lateral soft tissue neck radiographs (airway films) are abnormal in 92% of children, whereas chest radiographs are abnormal in only 58%.

373.3 Bronchial Foreign Bodies

Posteroanterior and lateral chest radiographs are indicated for the assessment of infants and children suspected of having aspirated a foreign object. The abdomen should be included in the field. During expiration the bronchial foreign body obstructs the exit of air from the obstructed lung, producing obstructive emphysema (air trapping) with persistent inflation of the obstructed lung and shift of the mediastinum toward the opposite side (Fig. 373–1). Air trapping is an immediate complication, in contrast to atelectasis, which is a late finding. Lateral decubitus chest films or fluoroscopy may provide the same information but are unnecessary. History and physical examination determine the indication for bronchoscopy.

Chapter 374 - Laryngotracheal Stenosis, Subglottic Stenosis

Lauren D. Holinger

Laryngotracheal stenosis is the most frequent cause of airway obstruction requiring tracheostomy in infants. The glottis (vocal cords) and the upper trachea are also compromised in most laryngeal stenoses, particularly those resulting from endotracheal intubation. Subglottic stenosis is considered to be congenital when there is no other apparent cause, such as a history of laryngeal trauma.

374.1 Congenital Subglottic Stenosis

See Chapter 372.2 .

374.2 Acquired Laryngotracheal Stenosis

Ninety per cent of acquired stenoses are related to endotracheal intubation. When the pressure of the endotracheal tube against the mucosa is greater than the capillary pressure, ischemia occurs, followed by necrosis and ulceration. Secondary infection and perichondritis develop with exposure of cartilage. Granulation tissue forms around the ulcerations. These changes and edema throughout the larynx usually resolve spontaneously after extubation. Fortunately, chronic edema and fibrous stenosis develop in only a small percentage.

Factors that predispose to the development of laryngeal stenosis include the following:

1. Laryngopharyngeal reflux of acid and pepsin from the stomach exacerbates endotracheal tube trauma. More damage is caused in areas left unprotected, owing to loss of mucosa.
2. Congenital subglottic stenosis narrows the larynx and is more likely to be traumatized by an endotracheal tube of age-appropriate size.
3. Other patient factors include sepsis and infection, dehydration, malnutrition, chronic inflammatory disorders, and immunosuppression.
4. An oversized endotracheal tube is the most common cause of laryngeal injury. A tube that allows a small air leak at the end of the inspiratory cycle minimizes potential trauma.
5. Other extrinsic factors include traumatic intubation, multiple reintubations, movement of the endotracheal tube, and duration of intubation.

The *clinical manifestations* of acquired and congenital stenosis (see Chapter 372.2) are similar. Spasmodic croup, the sudden onset of severe croup in the early morning hours, may occur owing to an episode of laryngopharyngeal reflux with transient laryngospasm and subsequent laryngeal edema. These frightening episodes resolve rapidly, often before the family and child reach the emergency department.

The *diagnosis* is confirmed by bronchoscopy.

Treatment is based on the severity, location, and type (cartilaginous or soft tissue) of the stenosis. Mild cases can be managed without operative intervention because the airway will improve as the child grows. Moderate soft tissue stenosis is treated by endoscopy using gentle dilations or CO_2 laser. Severe laryngotracheal stenosis is likely to require laryngotracheal expansion surgery or resection of the narrowed portion of the laryngeal and tracheal airway (cricotracheal resection). Every effort should be made to avoid tracheotomy using endoscopic techniques or open surgical procedures such as the anterior laryngotracheal decompression (cricoid split).

Chapter 375 - Congenital Anomalies of the Trachea and Bronchi

Lauren D. Holinger

Congenital anomalies of the trachea, bronchi, and lungs can create serious respiratory difficulties from the first minutes of life. These intrathoracic lesions typically cause obstructive emphysema, atelectasis, or expiratory wheezing, frequently masquerading as asthma. The expiratory wheezing contrasts to the inspiratory stridor caused by extrathoracic lesions such as congenital anomalies of the larynx. See Chapter 376 for discussion of bronchomalacia and tracheomalacia.

375.1 Vascular and Cardiac Anomalies

The *aberrant innominate artery* is the most common cause of secondary tracheomalacia. Expiratory wheezing and cough occur and, rarely, reflex apnea or "dying spells." Surgical intervention is rarely necessary. Infants are treated expectantly because the problem is self-limited.

The term *vascular ring* is used to describe vascular anomalies that result from abnormal development of the aortic arch complex (see Chapter 425).

Congenital cardiac defects may compress the left main bronchus or lower trachea. Any condition that produces significant pulmonary hypertension increases the size of the pulmonary arteries, which in turn cause compression of the left main bronchus. Correction of the underlying pathology relieves the airway compression.

375.2 Tracheal Stenoses, Webs, and Atresia

Congenital soft tissue stenoses and thin webs are rare. Dilation may be all that is required. Long-segment congenital tracheal stenosis with complete tracheal rings typically presents within the first year of life, usually after a crisis has been precipitated by an acute respiratory illness. The diagnosis may be suggested by plain radiographs. CT with contrast medium enhancement delineates associated intrathoracic anomalies such as the pulmonary artery sling, which occurs in one third of patients; one fourth have associated cardiac anomalies. Bronchoscopy is the best method to define the extent of the stenosis. With an adequate airway, surgical intervention is not necessary. When the severity of obstruction dictates surgical intervention, resection

of the narrowed segment and re-anastomosis will suffice for short segments. For long-segment congenital tracheal stenosis with complete tracheal rings, tracheoplasty or free tracheal autograft is undertaken with cardiopulmonary bypass.

Tracheal agenesis and atresia are rare anomalies that are incompatible with life. They are often associated with other congenital anomalies, particularly laryngeal conditions and tracheoesophageal fistula. The diagnosis is made by bronchoscopy in the newborn with severe respiratory distress.

375.3 Foregut Cysts

The bronchogenic cyst, intramural esophageal cyst (esophageal duplication), and enteric cyst may all produce symptoms of respiratory obstruction and dysphagia. The diagnosis is suspected when chest radiographs or CT scan delineate the mass and, in the case of enteric cyst, the associated vertebral anomaly. The treatment of all foregut cysts is surgical excision.

Chapter 376 - Bronchomalacia and Tracheomalacia

Jonathan D. Finder

Chondromalacia of the trachea or of a main bronchus, in which there is insufficient cartilage to maintain the airway patency, is a common cause of persistent wheezing in infancy. Primary tracheomalacia and bronchomalacia is more common than secondary tracheomalacia and bronchomalacia, in which the chondromalacia is secondary to compression by adjacent structure (e.g., vascular ring) or to tracheoesophageal fistula. Laryngomalacia may accompany primary bronchomalacia or tracheomalacia (see also Chapter 372.1). Involvement of the entire central airway (laryngotracheobronchomalacia) is also seen.

Clinical Manifestations.

Primary tracheomalacia and bronchomalacia is principally a disease of infants. The dominant finding, low-pitched wheezing, is most prominent over the central airways. When the lesion involves only one main bronchus (commonly the left), the wheezing is louder on that side, and delayed air entry can be detected with a double-headed stethoscope. In cases of tracheomalacia, the wheeze is loudest over the trachea. Hyperinflation and/or subcostal retraction do not occur unless the patient also has asthma or another cause of small airways obstruction. Thus, most patients do not improve with use of bronchodilators. It is common for ß-adrenergic agents to cause worsening. Acquired tracheomalacia and bronchomalacia is seen in association with vascular rings, following repair of tracheoesophageal fistula, cardiomegaly, and after lung transplantation.

Diagnosis.

Pulmonary function testing may show flattening of the flow-volume loop, but this is not a constant feature. The lesion is difficult to detect on plain radiographs, but fluoroscopy may demonstrate dynamic collapse and can avoid the need for invasive diagnostic techniques. Definitive diagnosis is by flexible bronchoscopy. Other important diagnostic modalities include MRI and CT scanning. MRI is especially useful when there is a possibility of vascular ring and should be performed when a right aortic arch is seen on plain film radiography.

Treatment.

Postural drainage may help with clearance of secretions. ß-adrenergic agents should be avoided, but nebulized ipratropium bromide may be useful. Endobronchial stents have been used in severely affected patients but have a high incidence of complications, ranging from airway obstruction from granulation tissue to erosion into adjacent vascular structures. Constant positive airway pressure (CPAP) or mechanical ventilation via tracheostomy may be indicated for severe cases.

Prognosis.

Primary bronchomalacia and tracheomalacia has a good prognosis, because airflow improves as the airways grow. Wheezing at rest is usually gone by age 5 yr. Patients with concurrent asthma need considerable supportive treatment.

Chapter 377 - Neoplasms of the Larynx, Trachea, and Bronchi

Lauren D. Holinger

377.1 Vocal Nodules

Although vocal nodules are not true neoplasms, they are mentioned here because they are the most common cause of chronic hoarseness in children. Chronic vocal abuse or misuse produces nodules at the junction of the anterior and middle thirds of the phonating edge of the vocal cords. These symmetric, bilateral swellings interfere with voice production and cause children to strain the voice. Vocal nodules can occur in infants and are exacerbated by laryngopharyngeal reflux.

Voice therapy may be effective in the cooperative child, but for most toddlers and older children behavioral therapy is necessary. Nodules usually resolve by early teenage years as the child matures and vocal abuse is moderated. Surgical excision is rarely indicated but may be necessary if the child is unable to communicate adequately or becomes aphonic or if tension and straining is necessary to make any utterances.

Laryngopharyngeal reflux commonly exacerbates vocal abuse, adding to swelling of the vocal cords. When vocal abuse is the main factor, the voice is worse in the evenings; with laryngopharyngeal reflux, hoarseness is worse in the morning. An antireflux regimen is indicated.

377.2 Recurrent Respiratory Papillomatosis (RRP)

Epidemiology and Etiology.

Papillomas are the most common respiratory tract neoplasms in children, occurring in 4.3 per 100,000. They are simply warts—benign tumors—caused by the human papillomavirus (HPV); the same pathology is found in condylomata acuminata (vaginal warts). HPV types 6 and 11 are most commonly associated with laryngeal disease. Fifty per cent occur in children younger than 5 yr, but the diagnosis may be made at any age. Of children with RRP, 67% are born

to mothers who had condylomata during pregnancy or parturition. The risk for transmission is about 1 in 500 vaginal births in mothers with active condylomata. Neonates have been reported to have RRP, which suggests intrauterine transmission of HPV.

Clinical Manifestations.

These benign squamous lesions can produce chronic hoarseness in the infant. Most occur in the larynx, specifically on the vocal cords, but in 31% these lesions occur in other areas of the respiratory tract: nose, pharynx (especially the uvula and posterior soft palate), trachea, bronchi, and lungs. As growth on the vocal cords progresses, hoarseness increases and communication becomes difficult. Respiratory distress develops. Symptoms often occur first during sleep with symptoms typical of obstructive sleep apnea. Progressive respiratory distress with sleep, exertion, daily activities, and finally at rest indicates the need for surgical intervention.

Treatment.

The treatment of RRP is endoscopic surgical removal. Most surgeons in North America prefer excision with the CO_2 laser. Surgical excision is a quality of life issue warranting removal to improve the voice. Intervention becomes a medical necessity when airway obstruction progresses. Laryngopharyngeal reflux may require treatment when reflux laryngitis is a factor. Other types of medical management including injection of cidofovir may have some benefit.

377.3 Congenital Subglottic Hemangioma

Typically, hemangiomas are symptomatic within the first 2 mo of life, with almost all presenting before 6 mo of age. Stridor is biphasic but usually more prominent during inspiration. The infant may be hoarse, have a barking cough, and present with croup. Of congenital subglottic hemangiomas, 50% are associated with cutaneous lesions. Radiographs classically delineate an asymmetric subglottic narrowing. The diagnosis is made by direct laryngoscopy.

Medical management includes systemic steroids. Prednisone, 2–4?mg/kg/24?hr, is given orally for 4–6 wk, less if the lesions stabilize sooner. The dosage is then tapered. If there is no response, the drug is discontinued. Interferon alfa-2a has also been recommended for the treatment of life-threatening corticosteroid-resistant hemangiomas that involve the airway and endanger vital structures.

Although tracheostomy establishes a safe airway, every effort should be made to find an alternative. Corticosteroids can be injected directly into the lesion. Endoscopic excision with the CO_2 laser is effective. Combining several modalities increases the possibility of avoiding tracheotomy. External surgical excision is suitable for some lesions.

377.4 Vascular Anomalies

Vascular malformations are not true neoplastic lesions. They have a normal rate of endothelial turnover and various channel abnormalities. They are categorized by their predominant type (capillary, venous, arterial, lymphatic, or a combination). Slow-flow malformations have capillary, lymphatic, or venous components. These were incorrectly called capillary hemangiomas, cystic hygromas or lymphangiomas, and cavernous hemangiomas, respectively.

Lymphatic malformations (cystic hygromas) rarely occur in the larynx. When they do, they are invariably an extension of disease from the head and neck. Airway obstruction may necessitate tracheostomy. The lesion can be debulked with the CO_2 laser.

377.5 Other Laryngeal Neoplasms

Neurofibromatosis rarely involves the larynx. When children are affected, limited local resection is undertaken to maintain an airway and optimize the voice. Complete surgical extirpation is virtually impossible without debilitating resection of vital laryngeal structures. Most surgeons select the option of less aggressive symptomatic surgery because of the poorly circumscribed and infiltrative nature of these fibromas. Rhabdomyosarcoma and other malignant tumors of the larynx are rare. Symptoms of hoarseness and progressive airway obstruction prompt initial evaluation by flexible laryngoscopy in the office.

377.6 Tracheal Neoplasms

The majority of tracheal tumors are benign; the two most common are inflammatory pseudotumor and hamartoma. The inflammatory pseudotumor is probably a reaction to a previous bronchial infection or traumatic insult. Growth is slow, and the tumor may be locally invasive. Hamartomas are tumors of primary tissue elements that are abnormal in proportion and arrangement.

Tracheal neoplasms present with stridor, wheezing, cough, or pneumonia and are rarely diagnosed until 75% of the lumen has been obstructed. Symptoms mimic asthma and are frequently misdiagnosed as such. Chest radiographs or airway films may identify the obstruction. Pulmonary function studies demonstrate an abnormal flow-volume loop. A mild response to bronchodilator therapy may be misleading.

377.7 Bronchial Tumors

Bronchial tumors are rare; two thirds are malignant. Bronchial “adenomas” are the most common, representing 30% of all lung tumors. Bronchogenic carcinoma is the second most common and occurs in approximately 20% of cases. The diagnosis is confirmed at bronchoscopy and biopsy; treatment depends on the histopathology.

Chapter 378 - Inflammatory Disorders of the Small Airways

Denise Goodman

378.1 Bronchitis

Bronchitis refers to nonspecific bronchial inflammation and is associated with a number of childhood conditions. *Acute bronchitis* is a syndrome, usually viral in origin, with cough as a prominent feature.

Acute tracheobronchitis is a term used when the trachea is prominently involved. Nasopharyngitis may also be present, and a variety of viral and bacterial agents, such as those causing

influenza, pertussis, and diphtheria, may be responsible. Isolation of common bacteria such as pneumococcus, *Staphylococcus,* and *Streptococcus* from the sputum may not imply a bacterial cause requiring antibiotic therapy.

Asthmatic bronchitis is an obsolete term; wheezing and bronchial inflammation are integral findings of asthma, and asthma exacerbations are commonly triggered by upper respiratory tract infections. Thus, use of the term *asthmatic bronchitis* may obscure the understanding on the part of patient and family that this is asthma.

ACUTE BRONCHITIS

Clinical Manifestations.

Acute bronchitis is commonly preceded by a viral upper respiratory tract infection. Thus, it is more common in the winter when respiratory viral syndromes predominate. The tracheobronchial epithelium is invaded by the infectious agent, leading to activation of inflammatory cells and release of cytokines. Constitutional symptoms, such as fever and malaise, follow. The tracheobronchial epithelium may become significantly damaged or hypersensitized, leading to a protracted cough lasting 1–3 wk.

Commonly, the child first presents with nonspecific upper respiratory infectious symptoms, such as rhinitis. Three to 4 days later, a frequent, dry, hacking cough develops, which may or may not be productive. After several days, the sputum may become purulent, but purulent sputum indicates leukocyte migration and does not necessarily imply bacterial infection. Many children swallow their sputum, and this may produce emesis. Chest pain may be a prominent complaint in older children, exacerbated by coughing. The mucus gradually thins, usually within 5–10 days, and then the cough gradually abates. The entire episode usually lasts about 2 wk and seldom longer than 3 wk.

Findings on physical examination vary with age of the patient and stage of the disease. Early findings are absent or low-grade fever and upper respiratory signs such as nasopharyngitis, conjunctivitis, and rhinitis. Auscultation of the chest may be unremarkable at this early phase. As the syndrome progresses and cough worsens, breath sounds become coarse, with coarse and fine crackles and scattered high-pitched wheezing. Chest radiographs are normal or may have increased bronchial markings.

The principal objective of the clinician is to exclude pneumonia, which is more likely caused by bacterial agents requiring antibiotic therapy. In at least one study of adults, absence of abnormality of vital signs (tachycardia, tachypnea, fever) and chest examination reduced the likelihood of pneumonia.

Differential Diagnosis.

Persistent or recurrent symptoms should lead the clinician to consider entities other than acute bronchitis. Many entities may manifest with cough as a prominent symptom. See also Chapter 370 and Box 370–2 .

Treatment.

There is no specific therapy for acute bronchitis. The disease is self-limited, and antibiotics, although frequently prescribed, do not hasten improvement in uncomplicated acute bronchitis. Frequent shifts in position may facilitate pulmonary drainage in infants. Older children are sometimes more comfortable with humidity, but this does not shorten the disease course. Cough suppressants may produce symptomatic relief but may also increase the risk of suppuration and inspissated secretions and therefore should be used judiciously. Antihistamines dry secretions and are not helpful, and expectorants are likewise not indicated.

CHRONIC BRONCHITIS

Chronic bronchitis is well recognized in adults, formally defined as 3 mo or more of productive cough each year for 2 yr or more. The disease may develop insidiously, with episodes of acute obstruction alternating with quiescent periods. A number of predisposing conditions may lead to progression of airflow obstruction or chronic obstructive pulmonary disease (COPD), with smoking as the major factor (up to 80% of patients have a smoking history). Other conditions include air pollution,

occupational exposures, and repeated infections.

The applicability of this definition to children is unclear. The existence of chronic bronchitis as a distinct entity in children is controversial. However, like adults, children with chronic inflammatory diseases or those with toxic exposures may develop damaged pulmonary epithelium. Thus, chronic or recurring cough in children should guide the clinician to search for underlying pulmonary or systemic disorders such as those summarized earlier in Box 370–2 .

CIGARETTE SMOKING AND AIR POLLUTION

Exposure to environmental irritants, such as tobacco smoke and air pollution, can incite or aggravate cough. There is a well-established association between tobacco exposure and pulmonary disease, including bronchitis and wheezing. This may occur either through cigarette smoking or by exposure to passive smoke. Marijuana smoke is another irritant sometimes overlooked when eliciting a history.

A number of pollutants are also likely candidates as precipitants of lung disease, including particulate matter, ozone, and nitrogen dioxide. Because these substances coexist in the atmosphere, the relative contribution of any one to pulmonary symptoms is difficult to discern.

378.2 Bronchiolitis

Acute bronchiolitis is a common disease of the lower respiratory tract in infants, resulting from inflammatory obstruction of the small airways. By age 2 yr nearly all children have been infected, with severe disease more common among infants aged 1–3 mo. Bronchiolitis is seasonal, with peak activity during winter and early spring.

Etiology and Epidemiology.

Acute bronchiolitis is predominantly a viral disease. Respiratory syncytial virus (RSV) is responsible for more than 50% of cases. Other agents include parainfluenza,

adenovirus, *Mycoplasma,* and occasionally other viruses. There is no evidence of a bacterial cause for bronchiolitis, although bacterial pneumonia is sometimes confused clinically with bronchiolitis and bronchiolitis may be followed by bacterial superinfection.

Estimates suggest that 50,000–80,000 of hospitalizations annually among children younger than 1 yr are attributable to RSV infection, representing an increase over the past decade. This increase may reflect increased attendance of infants in daycare centers, changes in criteria for hospital admission, and/or improved survival of premature infants and others at risk for severe RSV-associated disease.

Bronchiolitis is more common in males, in those who have not been breast-fed, and in those who live in crowded conditions. Older family members are a common source of infection but may experience only minor respiratory symptoms. The clinical manifestations of lower respiratory tract illness (LRTI) seen in young infants may be minimal in older patients, in whom bronchiolar edema is better tolerated.

Pathophysiology.

Not all infected infants develop LRTI. Host anatomic and immunologic factors seem to play a significant role in the severity of the clinical syndrome. Infants with pre-existent smaller airways and diminished lung function have a more severe course. In addition, RSV infection incites a complex immune response. Eosinophils

degranulate and release eosinophil cationic protein, which is cytotoxic to airway epithelium. IgE antibody release may be related to wheezing. Other mediators invoked in the pathogenesis of airway inflammation include chemokines such as interleukin-8 (IL-8), macrophage-inflammatory protein (MIP) 1a, and RANTES (Regulated on Activation, Normal T-cell Expressed and Secreted). RSV-infected infants who wheeze express higher levels of interferon-? in the airway as well as leukotrienes. Additionally, altered regulation of surfactant proteins A and B may exacerbate the abnormal lung function of infants with bronchiolitis. These findings suggest a complex cellular dysregulation producing the clinical syndrome.

Acute bronchiolitis is characterized by bronchiolar obstruction with edema, mucus, and cellular debris. Even minor bronchiolar wall thickening significantly affects airflow because resistance is inversely proportional to the fourth power of the radius of the bronchiolar passage. Resistance in the small air passages is increased during both inspiration and exhalation, but because the radius of an airway is smaller during expiration, the resultant ball valve respiratory obstruction leads to early air trapping and overinflation. If obstruction is complete with resorption of trapped air, the child will develop atelectasis.

These cellular and pathologic processes impair normal pulmonary gas exchange. Hypoxemia is a consequence of ventilation-perfusion mismatch early in the course. With severe disease, hypercapnia develops.

Clinical Manifestations.

The illness is usually preceded by exposure to an older contact with a minor respiratory syndrome within the previous week. The infant first develops a mild upper respiratory tract infection with sneezing and clear rhinorrhea. This may be accompanied by diminished appetite and fever of 38.5–39℃ (101–102℉), although the temperature may range from subnormal to markedly elevated. Gradually, respiratory distress ensues, with paroxysmal wheezy cough, dyspnea, and irritability. The infant is often tachypneic, which interferes with feeding. The child does not usually have other systemic complaints, such as diarrhea or vomiting. Apnea may be more prominent than wheezing early in the course of the disease, particularly with very young infants.

The physical examination is characterized most prominently by wheezing. The degree of tachypnea does not always correlate with the degree of hypoxemia or hypercarbia, so the use of pulse oximetry and noninvasive carbon dioxide determination is essential. Work of breathing may be markedly increased, with nasal flaring and retractions. Auscultation may reveal fine crackles or overt wheezes, with prolongation of the expiratory phase of breathing. Barely audible breath sounds suggest very severe disease with nearly complete bronchiolar obstruction. Hyperinflation of the lungs may permit palpation of the liver and spleen.

Chest radiography reveals hyperinflated lungs with patchy atelectasis. This may be difficult to distinguish from early bacterial pneumonia.

The white blood cell and differential counts are usually normal, without the lymphopenia seen with other viral illnesses. The utility of viral testing (usually rapid immunofluorescence, polymerase chain reaction, or viral culture) is debatable. The diagnosis is clinical, particularly in a previously healthy infant presenting with a first-time wheezing episode during a community outbreak. However, because concurrent bacterial infection is highly unlikely, confirmation of viral bronchiolitis may obviate the need for a sepsis evaluation in a febrile infant.

Differential Diagnosis.

The condition most commonly confused with acute bronchiolitis is asthma. The two conditions may not be distinguishable during the first episode, but repeated episodes of wheezing, absence of a viral prodrome, and presence of a family history of atopy or asthma supports a diagnosis of asthma. Other entities that may be confused with bronchiolitis in young infants include foreign body in the trachea, tracheo- or bronchomalacia, vascular rings, congestive heart failure, cystic fibrosis, or pertussis.

Course and Prognosis.

During the first 48–72?hr after onset of cough and dyspnea the infant is at highest risk for further respiratory compromise; he or she may be desperately ill with air hunger, apnea, and respiratory acidosis. The case fatality rate is less than 1%, with death attributable to apnea, uncompensated respiratory acidosis, or severe dehydration. After this critical period, symptoms may persist. In one study of ambulatory children in South Africa, the median duration of symptoms was 12 days. Infants with conditions such as congenital heart disease, bronchopulmonary dysplasia, and immunodeficiency often have more severe disease, with higher morbidity and mortality.

Recurrent Wheezing after Bronchiolitis.

Epidemiologic studies with several year follow-up of index and control children show a higher incidence of wheezing and asthma in children with a history of bronchiolitis, unexplained by family history or other atopic syndromes. It is unclear whether bronchiolitis incites an immune response that manifests as asthma later or whether those infants have an inherent predilection for asthma that is merely unmasked by their episode of RSV.

Treatment.

Infants with respiratory distress should be *hospitalized*; the mainstay of treatment is supportive. If hypoxemic, the child should receive *cool humidified oxygen*. Sedatives are to be avoided because they may depress respiratory drive. The infant is sometimes more comfortable if *sitting with head and chest elevated at a 30-degree angle with neck extended*. The risk of aspiration of oral feedings may be high in infants with bronchiolitis owing to tachypnea and the increased work of breathing. The infant may be fed through a nasogastric tube. However, if there is any risk for further respiratory decompensation potentially necessitating tracheal intubation, the infant should be kept *NPO and maintained with parenteral fluids*.

A number of agents have been proposed as adjunctive therapies for bronchiolitis. *Bronchodilators* produce modest short-term improvement in clinical features, but the statistical improvement in clinical scoring systems seen with them is not always

clinically significant. Several studies have included both infants with first-time and recurrent wheezing, complicating interpretation of the data. Nebulized epinephrine may be more effective than ß-agonists. A trial dose of inhaled bronchodilator may be

reasonable, with further therapy predicated on response in the individual patient.

Corticosteroids, whether parenteral, oral, or inhaled, are widely used despite conflicting studies. Differences of diagnostic criteria, measures of effect, timing and route of administration, and severity of illness complicate these studies. In a meta-analysis of steroid use, pooling of all studies and length-of-stay (LOS) plus duration-of-symptoms as outcomes yielded mean reduction in LOS of less than 1 day per patient. This effect disappeared if studies were used measuring LOS only or clearly excluding patients with previous episodes of wheezing. Thus, the theoretical benefits of corticosteroids do not outweigh their risks, side effects, and expense, and they are not indicated for previously healthy infants with RSV.

Ribavirin, an antiviral agent administered by aerosol, has been used for infants with congenital heart disease or chronic lung disease. There is no convincing evidence of a positive impact on clinically important outcomes such as mortality and duration of hospitalization. *Antibiotics* have no value unless there is secondary bacterial pneumonia. Likewise, there is no support for *RSV immune globulin* administration during acute episodes of RSV bronchiolitis.

Prevention.

Pooled hyperimmune RSV intravenous immunoglobulin (RSV-IVIG, RespiGam) and palivizumab, (Synagis) an intramuscular monoclonal antibody to the RSV F protein are effective in preventing severe RSV disease in high-risk infants when given before and during RSV season. Palivizumab is recommended for infants younger than age 2 yr with chronic lung disease (bronchopulmonary dysplasia) or prematurity. Because of increased mortality after RespiGam administration to infants with symptomatic cyanotic congenital heart disease, the best approach to this population is still under investigation. Meticulous handwashing is the best measure to prevent nosocomial transmission.

Chapter 379 - Wheezing in Infants

Marzena Krawiec
Robert F. Lemanske Jr.

In infants and young children, wheezing is common owing to unique age-specific anatomic and physiologic properties and gender-specific intrinsic lung characteristics (Table 379–1). The etiology of wheezing involves any pathophysiologic process resulting in impaired airflow mediated by a reduction in airway diameter. This pathophysiologic end-point encompasses a variety of causes and therefore poses diagnostic difficulties in the evaluation of the young wheezing child younger than age 5 yr (Table 379–2). Nonetheless, the most common causes of infantile wheezing are viral respiratory infections and asthma (for a fuller discussion of asthma, see Chapter 134).

Factors contributing to the development of asthma in early wheezing children are poorly understood. Based both on the onset and the pattern of wheezing, young children have been grouped into three wheezing phenotypes (see Table 379–2). The most important distinction among these groups is lower morbidity in the transient wheezing phenotype compared with the child with persistent wheezing. Children in this latter group have significantly higher morbidity, including irreversible loss of lung function by age 6 yr. In addition, significant airway inflammation can be found in the airways of recurrent wheezing infants, suggesting that pathophysiologic features associated with adult asthma may be starting at a very young age. However, although 20% of all children will have had at least one wheezing illness by 1 yr of age, almost 33% by 3 yr of age, and nearly 50% by 6 yr, less than 15% of children are subsequently diagnosed with asthma based on symptoms of recurrent wheezing, airway obstruction, and hyperresponsiveness. Nevertheless, asthma is the most common disease of childhood and confers a significant degree of morbidity, thereby demanding early evaluation and management in the predisposed persistently wheezing infant.

Pathophysiology.

Both virus-specific and host-specific factors are likely to contribute to the clinical expression of the different wheezing phenotypes during early childhood. Virus-specific factors include the ability to preferentially affect the lower airway, to generate virus-specific IgE antibody (e.g., respiratory syncytial virus [RSV]), and to induce specific cytokine responses to various viruses and viral proteins. Host-specific factors vary based on the wheezing phenotype. Specifically, lung size is the primary factor associated with the transient wheezing phenotype, whereas parental history of asthma, elevated serum IgE levels, and the presence of atopic dermatitis are associated with the persistent wheezing phenotype. Exposure to passive smoke is a significant risk factor for both phenotypes.

The presence of atopy in the host and the development of lower respiratory tract infections are the two most important independent risk factors for the development of persistent wheezing and asthma. In addition, the atopic state can influence lower airway response to viral infections, whereas viral infections may influence the development of allergy, and interactions can occur based on simultaneous exposure to both allergens and viruses. Infection with RSV is the cause of the majority of lower respiratory tract illnesses with wheezing during the first 3 yr of life and may increase the risk of allergic sensitization later in childhood. Furthermore, diminished levels of lung function have been found years later after only a single episode of lower respiratory tract infection during infancy. The variability in clinical outcomes concerning the inception of allergic respiratory diseases may be related to the severity, viral pathogen, and/or

TABLE 379-1 -- **Pathophysiologic Properties Predisposing Infants and Young Children to Wheeze**

	Effect
Physiologic Properties in Infants Relative to Older Children/Adults	
?Bronchial smooth muscle content	?Structural support
	?Risk of atelectasis
Hyperplasia of bronchial mucus glands	?Mucus production
	?Risk of obstruction
?Radius of conducting airways resulting in overall ? turbulent flow[*]	?Conductance
	?Filtration of particles
	?Risk of obstruction
	?Risk of atelectasis
?Resistance in peripheral airways due to decreased airway size[†]	?Risk of obstruction
	?Work of breathing
?Chest wall compliance	?Work of breathing
Diaphragm	
Horizontal insertion of the diaphragm to the rib cage	
? Number of fatigue-resistant skeletal muscle fibers	?Risk of atelectasis distal to obstruction

Deficient collateral ventilation	
Gender-Based Properties Related to Infantile Wheeze	
Females	?Lung size
Males	?Airway conductance (?V_{max} FRC)

**Airflow occurs in three forms: laminar, turbulent, and transitional based on the size of the airway. Laminar flow occurs primarily in the small airways, whereas turbulent flow occurs in the central airways. Turbulent flow facilitates the filtration of inhaled particles in conjunction with mucociliary clearance mechanisms. Because of the marked decrease in radial size of the proximal airways in infants compared with adults, there is less turbulent flow in infants, prediposing them to less effective filtration and clearance of particles, resulting in airflow obstruction.*

†Poiseuille's equation states that resistance to airflow through a tube is inversely related to the radius to the fourth power. Therefore, any disease that decreases the diameter of the small airways can lead to increased obstruction owing to heightened airflow resistance.

timing of the initial infection and its relationship to concurrent or subsequent allergen exposures.

Clinical Manifestations.

A careful history and physical examination are critical in the approach to the child with recurrent wheezing in infancy. In terms of a potential predisposition to clinical asthma, findings on history include the number and frequency of wheezing episodes, the relationship of the episode to viral infection and/or aeroallergen exposures, the presence of allergic diseases such as conjunctivitis, rhinitis, and/or eczema, and parental history of asthma. On physical examination, the following points deserve emphasis: (1) the overall appearance of the child based on an assessment of respiratory distress and the work of breathing; (2) whether there is wheezing, transmitted upper airway nasal congestion, stridor and wheezing (suggestive of both an upper and lower airway process such as croup, tracheomalacia, or bronchomalacia), or wheezing and crackles (suggestive of an interstitial lung component including infection, bronchopulmonary dysplasia [BPD], or pulmonary edema with congestive heart disease [CHD]); and (3) the location of wheezing (unilateral, suggestive of a foreign body or bronchomalacia, or bilateral, suggestive of a more generalized process).

Any young child with increased work of breathing manifested by an increased respiratory rate and/or intercostal/subcostal retractions should raise concern. More commonly in infants, respiratory distress may manifest as “abdominal or belly breathing” along with chest wall retractions. In general, children who will ultimately fall in the transient wheezing category will not have wheezing episodes associated with significant respiratory distress and/or hypoxia. Additional findings on physical examination that may provide insight into the etiology of infantile wheeze include (1) the child's growth curve (evidence of poor weight gain suggests other causes of wheezing such as cystic fibrosis, immunodeficiency, and/or gastroesophageal reflux disease [GERD]), (2) clinical features such as rhinitis and/or conjunctivitis and the presence of eczema (findings suggestive of atopy, a risk factor for the development of persistent wheezing), and (3) the presence of a central or midline structural or cutaneous lesion such as a hemangioma (associated with an increased risk of an intrathoracic lesion).

Laboratory Findings.

Radiologic assessment should vary based on the initial presentation of the child. Most infants with a single episode of wheezing will not require a chest radiograph, other than to confirm positive additional findings and/or to alleviate parental anxieties. In contrast, any child with recurrent episodes of wheezing or congenital anomalies should have anteroposterior and lateral radiographic views taken to ascertain the presence of hyperinflation and/or structural abnormalities, respectively. Furthermore, suspicion of structural abnormalities may warrant additional imaging studies such as a CT or MRI and/or direct visualization using laryngobronchoscopy. Additional laboratory considerations in the patient with an atopic family history and/or physical findings include immediate hypersensitivity skin and/or radioimmune allergosorbent (RAST) tests. Finally, infant pulmonary function testing may be utilized to assess decreased lung function. However, the degree of air flow limitation in the first 3 mo of life is not an informative predictor of children at risk for the subsequent development of asthma. Additional evaluations establishing the presence of airway hyperresponsiveness during this time period may be associated with an increased risk of asthma by 6 yr of age.

Treatment.

The treatment of infantile wheeze should be based on the underlying etiology. For viral-induced wheezing (e.g., with infection with RSV or parainfluenza virus), management involves the use of supplemental oxygen to treat hypoxemia and a trial of bronchodilators including acute support with racemic epinephrine. Systemic corticosteroids are not indicated for the treatment of acute viral bronchiolitis, and the role of inhaled corticosteroids used acutely remains controversial. Because many infants experience airway hyperresponsiveness for months to years after RSV infection, treatment with bronchodilators (in the clinically responsive child) and possibly

TABLE 379-2 -- Differential Diagnosis of Wheezing in Infancy

Infection

Interstitial Lung Disease, Including Bronchiolitis Obliterans
Foreign Body

a long-term medication such as an inhaled corticosteroid (nebulized or using a metered-dose inhaler with face mask) or a leukotriene-modifying agent may be considered.

Prognosis.

Although the majority (~60%) of children with early-onset wheezing will stop wheezing, a minority (~14%) are at significant risk for persistent asthma. Based on the Tucson Children's Respiratory Study's asthma predictive index (API), young children with frequent wheezing episodes may be identified who are potentially at increased risk for the development of persistent asthma. During the first 3 yr of life, children with a positive API, defined as frequent episodes of wheezing and one major criterion (parent with asthma or eczema) or two minor criteria (serum eosinophilia [= 4%], wheezing not associated with an upper respiratory infection, and/or physician diagnosed allergic rhinitis), have been shown to have 48% and 67% positive predictive values for asthma and persistent wheezing, respectively, at age 6 yr.

Conversely, a negative API inferred 92% and 77% negative predictive values for asthma and persistent wheezing, respectively. This index may be helpful (1) to facilitate early intervention (see Chapter 134) for the wheezing infant at heightened risk for the development of chronic asthma and (2) to provide reassurance in the management of the child with a negative API. Whether early identification leading to early intervention can modify asthma expression and/or progression is unclear.

Chapter 380 - Emphysema and Overinflation

Steven Boas
Glenna B. Winnie

Pulmonary emphysema is distention of air spaces with irreversible disruption of the alveolar septa. It may be generalized or localized, involving part or all of a lung. Overinflation is distention with or without alveolar rupture and is often reversible.

Compensatory overinflation may be acute or chronic and occurs in normally functioning pulmonary tissue when, for any reason, a sizable portion of the lung is removed or becomes partially or completely airless, which may occur with pneumonia, atelectasis, empyema, and pneumothorax.

Obstructive overinflation results from partial obstruction of a bronchus or bronchiole, when it becomes more difficult for air to leave the alveoli than to enter; there is a gradual accumulation of air distal to the obstruction, the so-called bypass, ball valve, or check valve type of obstruction (see Chapter 373).

LOCALIZED OBSTRUCTIVE OVERINFLATION

When a ball-valve type of obstruction partially occludes the mainstem bronchus, the entire lung becomes overinflated; individual lobes are affected when the obstruction is in lobar bronchi. Segments or subsegments are affected when their

individual bronchi are blocked. Localized obstructions that may be responsible for overinflation include foreign bodies and the inflammatory reaction to them, abnormally thick mucus (e.g., asthma, cystic fibrosis), endobronchial tuberculosis or tuberculosis of the tracheobronchial lymph nodes, and endobronchial or mediastinal tumors. When most or all of a lobe is involved, the percussion note is hyperresonant over the area, and the breath sounds are decreased in intensity. The distended lung may extend across the mediastinum into the opposite hemithorax. Under fluoroscopic scrutiny during exhalation, the overinflated area does not decrease in size, and the heart and the mediastinum shift to the opposite side because the unobstructed lung empties normally.

Unilateral hyperlucent lung may be associated with a variety of cardiac and pulmonary diseases of children, but in some patients, it occurs without easily demonstrable underlying active disease. More than half the cases follow one or more episodes of pneumonia; a rising titer to adenovirus has been documented in several children. This condition may follow bronchiolitis obliterans and may include obliterative vasculitis as well, accounting for the greatly diminished perfusion and vascular marking on the affected side.

Patients may present with *clinical manifestations* of pneumonia, but some are discovered only when a chest radiograph is obtained for an unrelated reason. A few patients have hemoptysis. Physical findings may include hyperresonance and a small lung with the mediastinum shifted toward the more abnormal lung. This condition has been labeled **Swyer-James**or **Macleod syndrome**. Some patients show a mediastinal shift away from the lesion with exhalation. CT scanning or bronchography may demonstrate bronchiectasis. In some patients, previous chest radiographs have been normal or have shown only an acute pneumonia, suggesting that a hyperlucent lung is an acquired lesion. No specific *treatment* is known; it may become less symptomatic with time.

Congenital lobar emphysema (CLE) may result in severe respiratory distress in early infancy and may be caused by localized obstruction. Familial occurrence has been reported. In 50% of cases, a cause of CLE can be identified. Congenital deficiency of the bronchial cartilage, external compression by aberrant vessels, bronchial stenosis, redundant bronchial mucosal flaps, and kinking of the bronchus caused by herniation into the mediastinum have been described as leading to bronchial obstruction and subsequent CLE.

Clinical manifestations usually become apparent in the neonatal period but may be delayed for as long as 5–6 mo in 5% of patients. Some patients remain undiagnosed until school age or beyond. Signs range from mild tachypnea and wheeze to severe dyspnea with cyanosis. CLE affects the upper and middle lobes, with the left upper lobe the most common site. The affected lobe is essentially nonfunctional because of the overdistention, and atelectasis of the ipsilateral normal lung may ensue. With further distention, the mediastinum is shifted to the contralateral side with impaired function seen as well (Fig. 380–1). A radiolucent lobe and a mediastinal shift are often revealed by radiographic examination.

Treatment by immediate surgery and excision of the lobe may be lifesaving when cyanosis and severe respiratory distress are present, but some patients respond to medical treatment. Some children with apparent congenital lobar emphysema have reversible overinflation, without the classic alveolar septal rupture implied in the term *emphysema*.

Overinflation of all three lobes of the right lung has been produced by anomalous location of the left pulmonary artery, which impinges on the right main stem bronchus. Hyperinflation also occurs in patients with the absent pulmonary valve type of tetralogy of Fallot and secondary aneurysmal dilatation of the pulmonary artery, which partially compresses the main stem bronchi. A number of neonates have

Figure 380-1 Congenital left upper lobe emphysema. Note the extension of the emphysematous lobe into the left lower lobe and its displacement of the mediastinum toward the right.

lobar overinflation while being treated for hyaline membrane disease with assisted ventilation, suggesting an acquired cause. Medical management with selective intubation of the unaffected bronchus or high-frequency ventilation has occasionally been successful and lobectomy avoided.

GENERALIZED OBSTRUCTIVE OVERINFLATION

Acute generalized overinflation of the lung results from widespread involvement of the bronchioles and is usually reversible. It occurs more commonly in infants than in children and may be secondary to a number of clinical conditions, including asthma, cystic fibrosis, acute bronchiolitis, interstitial pneumonitis, atypical forms of acute laryngotracheobronchitis, aspiration of zinc stearate powder, chronic passive congestion secondary to a congenital cardiac lesion, and miliary tuberculosis.

Pathology.

In chronic overinflation, many of the alveoli are ruptured and communicate with one another, producing distended saccules. Air may also enter the interstitial tissue (i.e., interstitial emphysema), resulting in pneumomediastinum and pneumothorax (see Chapter 403 and Chapter 404).

Clinical Manifestations.

Generalized obstructive overinflation is characterized by dyspnea, with difficulty in exhaling. The lungs become increasingly overdistended, and the chest remains expanded during exhalation. An increased respiratory rate and decreased respiratory excursion result from the overdistention of the alveoli and their inability to be emptied normally through the narrowed bronchioles. Air hunger is responsible for forced respiratory movements. Overaction of the accessory muscles of respiration results in retractions at the suprasternal notch, the supraclavicular spaces, the lower margin of the thorax, and the intercostal spaces. Unlike the flattened chest during inspiration and exhalation in cases of laryngeal obstruction, minimal reduction in the size of the overdistended chest during exhalation is observed. The percussion note is hyperresonant. On auscultation, the inspiratory phase is usually less prominent than the expiratory phase, which is prolonged and roughened. Fine or medium crackles may be heard. Cyanosis is more common in the severe cases.

Diagnosis.

Radiographic and fluoroscopic examinations of the chest assist in establishing the diagnosis. Both leaves of the diaphragm are low and flattened, the ribs are farther apart than usual, and the lung fields are less dense. The movement of the diaphragm during exhalation is decreased, and the excursion of the low, flattened diaphragm in severe cases is barely

discernible. The anteroposterior diameter of the chest is increased, and the sternum may be bowed outward.

BULLOUS EMPHYSEMA.

Bullous emphysematous blebs or cysts (pneumatoceles) result from overdistention and rupture of alveoli during birth or shortly thereafter, or they may be sequelae of pneumonia and other infections. They have been observed in tuberculosis lesions during specific antibacterial therapy. These emphysematous areas presumable result from rupture of distended alveoli, forming a single or multiloculated cavity. The cysts may become large and may contain some fluid; an air fluid level may be demonstrated on the radiograph. The cysts should be differentiated from pulmonary abscesses. In most cases, the cysts disappear spontaneously within a few months, although they may persist for a year or more. Aspiration or surgery is not indicated except in cases of severe respiratory and cardiac compromise.

SUBCUTANEOUS EMPHYSEMA.

Subcutaneous emphysema results from any process that allows free air to enter into the subcutaneous tissue. The most common causes include pneumomediastinum or pneumothorax. Additionally, it may be a complication of fracture of the orbit, permitting free air to escape from the nasal sinuses. In the neck and thorax, subcutaneous emphysema may follow tracheotomy, deep ulceration in the pharyngeal region, esophageal wounds, or any perforating lesion of the larynx or trachea. It is occasionally a complication of thoracentesis, asthma, or abdominal surgery. Air rarely may be formed in the subcutaneous tissues by gas-producing bacteria.

Tenderness over the site of emphysema and “crepitant” quality on palpation of the skin are classic manifestations. Subcutaneous emphysema is usually a self-limited process and requires no specific treatment. Minimization of activities that may increase airway pressure (i.e., cough, performance of high-pressure pulmonary function testing maneuvers) is recommended. Resolution occurs by resorption of subcutaneous air after elimination of its source. Rarely, dangerous compression of the trachea by air in the surrounding soft tissue requires surgical intervention.

Chapter 381 - a_1 -Antitrypsin Deficiency and Emphysema

Glenna B. Winnie
Steven Boas

Homozygous deficiency of a_1 -antitrypsin (a-AT) is an important cause of the early onset of severe panacinar emphysema in adults in the third and fourth decades of life and an important cause of liver disease in children, but it rarely causes pulmonary diseases in children (see Chapter 338.6). a_1 -Antitrypsin and other serum antiproteases are important in the inactivation of proteolytic enzymes released from dead bacteria or leukocytes in the lung. Deficiency of these antiproteases leads to an accumulation of proteolytic enzymes in the lung, resulting in destruction of pulmonary tissue with subsequent development of emphysema. The concentration of proteases (e.g., elastase) in the patients' leukocytes may also be an important factor in determining the severity of clinical pulmonary disease with a given level of a_1 -antitrypsin.

Clinical Manifestations.

The type and concentration of a_1 -antitrypsin are inherited as a series of codominant alleles on chromosomal segment 14q32.1. See Chapter 338.6 for discussion of genotypes and liver disease. Early adult-onset emphysema associated with a_1 -antitrypsin deficiency occurs most frequently with PiZZ, although Pi(null) (null) and, to a lesser extent, other mutant Pi types such as SZ have been associated with emphysema. Most patients who have the PiZZ defect have little or no detectable pulmonary disease during childhood. A few have very early onset of chronic pulmonary symptoms, including dyspnea, wheezing, and cough, and panacinar emphysema has been documented by lung biopsy results. Smoking greatly increases the risk of emphysema developing in mutant Pi types. Newborn screening to identify children with PiZZ phenotype does not affect parental smoking habits but does decrease smoking rates for affected adolescents.

Physical examination may reveal growth failure, an increased anteroposterior diameter of the chest with a hyperresonant percussion note, crackles if there is active infection, and clubbing. Severe emphysema may depress the diaphragm, making the liver and spleen more easily palpable. Chest radiograph reveals

overinflation with depressed diaphragms; chest CT may show more hyperexpansion in the lower lung zones and, occasionally, bronchiectasis. Serum immunoassay measures the low level of a_1 -antitrypsin, and electrophoresis reveals the phenotype. Genotype can be determined by polymerase chain reaction.

Treatment.

Therapy for a_1 -antitrypsin deficiency is replacement with enzyme derived from pooled human plasma. Normal serum levels are 180–280?mg/dL, but a level of 80?mg/dL is protective for emphysema, and this target level for augmentation therapy results in the appearance of the transfused antiprotease in pulmonary lavage fluid. This treatment is safe, because a_1 -antitrypsin is relatively heat-resistant and inactivation of hepatitis and other viruses is easily accomplished; severe toxicity has not been reported. The Food and Drug Administration has approved the use of purified blood-derived human enzyme for ZZ and null/null patients. However, the benefit of this therapy has not yet been clearly established, owing to lack of placebo-controlled trials demonstrating efficacy. Replacement therapy appears most beneficial for those with moderately severe obstructive lung disease (FEV_1 30–65% of predicted) or those with mild lung disease experiencing a rapid decline in lung function. Treatment has been hampered by limited supply of the enzyme, although a_1 -antitrypsin produced by recombinant DNA technology is also available and could alleviate the shortage. Direct delivery to the lung by aerosol appears to be effective and might decrease the total dose required, but controversy continues over its clinical use. Gene therapy offers promise, although the vectors tested either result in levels too low to be of clinical benefit or in only transient correction.

Nonspecific therapy includes aggressive treatment of pulmonary infection, routine use of pneumococcal and influenza vaccines, bronchodilators, and advice about the risks of smoking. Such treatment is also indicated for other members of the family found to have PiZZ phenotypes or null/null, even if they are asymptomatic. Persons with the MZ Pi type do not have an increased risk for the development of pulmonary disease. The clinical significance of the SZ Pi type is unknown, but nonspecific treatment seems reasonable. All persons with low levels of serum antiprotease should be warned that the eventual development of emphysema is partially related to environmental factors, including exposure to industrial fumes, respiratory tract infections, and particularly cigarette smoking. Although identification of affected individuals could help prevent development of obstructive lung disease, screening programs are suspended, owing to concerns about employment and health care insurance discrimination.

Chapter 382 - Other Distal Airway Diseases

Steven Boas

382.1 Bronchiolitis Obliterans

Bronchiolitis obliterans (BO) is a rare, chronic lung disease of the bronchioles and smaller airways. BO most commonly occurs in the pediatric population after respiratory infections (i.e., adenovirus, *Mycoplasma*, measles, influenza, pertussis). Other causes include connective tissue disease (i.e., juvenile rheumatoid arthritis, systemic lupus erythematosus, scleroderma), toxin fume inhalation, as well as a manifestation after lung and bone marrow transplantation. BO occurs in all age groups, and the prevalence in one pediatric autopsy series was 2 in 1,000.

Pathogenesis.

After the initial insult, inflammation affecting terminal bronchioles, respiratory bronchioles, and alveolar ducts may result in the obliteration of the airway lumen. Epithelial damage resulting in abnormal repair is characteristic of BO. Complete or partial obstruction of the airway lumen may result in air trapping or atelectasis. Bronchiolitis obliterans organizing pneumonia (BOOP) is a fibrosing lung disease that includes the histologic features of BO with extension of the inflammatory process from distal alveolar ducts into alveoli with proliferation of fibroblasts. Bronchiolitis obliterans syndrome (BOS) is a clinical entity that relates to graft deterioration after transplantation due to progressive airway disease that appears histologically similar to BO. However, the etiology of BOS is unclear and may be unrelated to the mechanisms responsible for BO in nontransplant patients.

Clinical Manifestations/Diagnosis.

Cough, fever, cyanosis, and respiratory distress followed by initial improvement may be the initial signs of BO. In this phase, BO is easily confused with pneumonia, bronchitis, or bronchiolitis. Progression of the disease may ensue with increasing dyspnea, cough, sputum production, and wheezing. Chest radiographs may be relatively normal compared with the extent of physical findings but may demonstrate hyperlucency and patchy infiltrates. Occasionally, a Swyer-James syndrome (unilateral hyperlucent lung) has developed. Pulmonary function tests demonstrate variable findings but typically show signs of airway obstruction. Ventilation-perfusion scans reveal a typical motheaten appearance of multiple matched defects in ventilation and perfusion. Chest CT often demonstrates patchy areas of hyperlucency and bronchiectasis. Open lung biopsy or transbronchial biopsy remain the best means of establishing the diagnosis of BO or BOOP.

Treatment.

No definitive therapy exists for BO. Administration of corticosteroids may be beneficial. Immunomodulatory agents such as tacrolimus and antithymocyte globulin have been utilized in post–lung transplant recipients with BO with variable success. For BOOP, use of oral corticosteroids for up to 1 yr has been advocated as first-line therapy for symptomatic and progressive disease. Patients with asymptomatic or nonprogressive BOOP can be observed.

Prognosis.

Some patients with BO experience rapid deterioration in their condition and die within weeks of the initial symptoms, but most nontransplant patients survive with chronic disability. Unlike in BO, total recovery is seen in 60–80% of patients with BOOP, although this depends on the underlying systemic disease. Relapse of BOOP can occur, especially if treatment is less than 1 yr and is amenable to repeat courses of oral corticosteroids. Unlike the more common idiopathic BOOP, progressive BOOP characterized by acute respiratory distress syndrome (ARDS) is rare but is aggressive in its clinical course leading to death.

382.2 Follicular Bronchitis

Follicular bronchitis (FB) is a lymphoproliferative lung disorder characterized by the presence of lymphoid follicles coursing alongside the airways (bronchi or bronchioles). FB is rare in children. Although the cause is unknown, an infectious etiology (viral) has been proposed. Onset of symptoms generally occurs by 6 wk of age and peaks between 6 and 18 mo. Cough, moderate respiratory distress, fever, and fine crackles are common clinical findings. Fine crackles generally persist over time, and recurrence of symptoms is common. Chest radiographs may be relatively benign initially (air trapping, peribronchial thickening) but evolve into the typical interstitial pattern. Chest CT may show a fine reticular pattern. Definitive diagnosis is made by open lung biopsy. Some individuals with FB may respond to therapy with corticosteroids. Prognosis is variable, with some individuals having significant progression of pulmonary disease and others developing only mild obstructive airway

disease.

382.3 Pulmonary Alveolar Microlithiasis

Approximately 400 cases of this unusual disorder have been reported. Although the underlying cause of pulmonary alveolar microlithiasis (PAM) is unknown, the disease is characterized by the formation of lamellar concretions of calcium phosphate or “microliths” within the alveoli, creating a classic pattern on the radiograph (Fig. 382–1).

Epidemiology and Etiology.

Although the mean age at time of diagnosis is in the mid 30s, the onset of the disease can occur during childhood. A strong familial association is seen in half of the

Figure 382.3-1 Radiograph of the chest of a 7-yr-old boy with pulmonary alveolar microlithiasis. (From Clark RB III, Johnson FC: Idiopathic pulmonary alveolar microlithiasis: A case report and brief review of the literature. *Pediatrics* 1961;28:650.)

reported cases, with a probable autosomal recessive pattern of inheritance. In some families a rapid progression of disease occurs. Environmental factors (i.e., sand) may play a role as well. An equal male and female frequency is noted. A relatively large proportion of patients with PAM have Turkish ancestry.

Clinical Manifestations.

When symptomatic, individuals with PAM usually complain of dyspnea on exertion and nonproductive cough. Physical examination of the lungs may reveal fine inspiratory crackles and diminished breath sounds. Clubbing occurs, although this is usually a more advanced sign. Discordance between the clinical and radiographic manifestations is common. Children are often asymptomatic on initial presentation. Complications of pneumothorax, pleural adhesions and calcifications, pleural fibrosis, apical bulla, and extrapulmonary sites of microliths have been reported (i.e., kidneys, prostate, sympathetic chain, and testes).

Diagnosis.

Chest radiography typically reveals bilateral infiltrates with a fine sandlike micronodular appearance or “sandstorm” appearance with greater density in the lower and middle lung fields (see Fig. 382–1). CT of the chest shows diffuse micronodular calcified densities with thickening of the microliths along the septa and around distal bronchioles, especially in the inferior and posterior regions. Diffuse uptake of technetium Tc 99m diphosphonate by nuclear scan has been reported. Open lung and transbronchial lung biopsy reveal 0.1–0.3?mm laminated calcific concretions within the alveoli. Although the alveoli are often normal initially, progression to pulmonary fibrosis with advancing disease usually ensues. Sputum expectoration may reveal small microliths, although this finding is not diagnostic for PAM and is not typically seen in children. Pulmonary function testing reveals restrictive lung disease with impaired diffusing capacity as the disease progresses, whereas exercise testing demonstrates arterial oxygen desaturation. The differential diagnosis includes sarcoidosis, miliary tuberculosis, hemosiderosis, healed disseminated histoplasmosis, pulmonary calcinosis, and metastatic pulmonary calcifications.

Treatment.

No specific treatment is effective, although some have used glucocorticosteroids, etidronate disodium, and bronchopulmonary lavage with limited success. Lung transplantation has been performed for this condition, although it is unknown whether the disease recurs after transplantation.

Prognosis.

Progressive cardiopulmonary disease may ensue leading to cor pulmonale, superimposed infections, and subsequent death in mid adulthood. Because of the familial nature of this disease, counseling and chest radiographs of family members are indicated.

Chapter 383 - Congenital Disorders of the Lung

Thomas P. Green
Jonathan D. Finder

383.1 Pulmonary Agenesis and Aplasia

Pulmonary agenesis differs from hypoplasia by the complete absence of a lung, whereas it differs from aplasia by the absence of a bronchial stump or carina with agenesis. Bilateral pulmonary agenesis is incompatible with life, presenting as severe respiratory distress and failure. Pulmonary agenesis is thought to be an autosomal recessive trait based on reports of patients with parental consanguinity. Unilateral agenesis or hypoplasia may have few symptoms and nonspecific findings, resulting in only one third of the cases being diagnosed during life. Symptoms tend to be related to central airway complications of stenosis and/or tracheobronchomalacia. In patients in whom the right lung is absent, the aorta can compress the trachea and lead to symptoms of central airway compression. For this reason, right lung agenesis has a higher morbidity and mortality than left lung agenesis. Pulmonary agenesis is often seen in association with other congenital anomalies, such as the VACTERL sequence, ipsilateral facial and skeletal malformations, and central nervous system and cardiac malformations. Compensatory growth of the remaining lung allows for improved gas exchange, but the mediastinal shift can lead to scoliosis and airway compression.

383.2 Pulmonary Hypoplasia

Pulmonary hypoplasia almost always occurs secondary to other intrauterine disorders that produce an impairment of normal lung development. Conditions such as deformities of the thoracic spine and rib cage (thoracic dystrophy), pleural effusions with fetal hydrops, cystic adenomatoid malformation, and congenital diaphragmatic hernia physically constrain the developing lung. Any condition that produces oligohydramnios (e.g., fetal renal insufficiency or prolonged premature rupture of membranes) may also lead to diminished lung growth. In these conditions, airway and arterial branching are inhibited, thereby limiting the capacity for capillary and gas exchange surface area. Pulmonary hypoplasia involves a decrease in both the number

of alveoli (up to 67%) and the number of airway generations (up to 50%). In some conditions, the hypoplasia is bilateral because of the presence of bilateral lung constraint, as occurs in oligohydramnios or thoracic dystrophy. However, large, unilateral lesions, such as congenital diaphragmatic hernia and cystic adenomatoid malformation, may displace the mediastinum and thereby produce a contralateral hypoplasia, although usually not as severe as that seen on the ipsilateral side.

Pulmonary hypoplasia is recognized in the newborn period either because the degree of hypoplasia is quite severe or because of the presentation of persistent pulmonary hypertension. In either case, mechanical ventilation and oxygen may be required to support gas exchange because of respiratory distress and hypoxia. Specific therapy to control the pulmonary hypertension, such as inhaled nitric oxide, may be useful. However, in cases of severe hypoplasia the limited capacity of the pulmonary circulation may be inadequate to sustain life. Occasionally, in circumstances that are not amenable to less invasive treatment and support, extracorporeal membrane oxygenation may provide gas exchange for a critical period of time and permit survival.

383.3 Cystic Adenomatoid Malformation

Cystic adenomatoid malformation is one of the most common pulmonary congenital anomalies. This disorder consists of hamartomatous or dysplastic lung tissue mixed with more normal lung and is usually confined to one lobe.

Pathology.

Three histologic patterns have been described, although the relationship between the histologic appearance and outcome is controversial. Type 1 is macrocystic and consists of a single or several large (greater than 2?cm in diameter) cysts lined with ciliated pseudostratified epithelium. The wall of the cyst contains smooth muscle cells and elastic tissue. One third of cases have mucus-secreting cells. Cartilage is rarely seen in the wall of the cyst. This type has a good prognosis for survival. Type 2 is microcystic and consists of multiple small cysts with similar histology to that of the type 1 lesion. Type 2 is associated with other congenital anomalies and carries a poor prognosis. In type 3, the lesion is solid with bronchiole-like structures lined with cuboidal ciliated epithelium and separated by areas of nonciliated cuboidal epithelium. This lesion carries the worst prognosis and may be incompatible with life.

The lesion probably results from an embryologic insult, before the 35th day of gestation, with maldevelopment of terminal bronchiolar structures. Histologic examination reveals little normal lung and many glandular elements. Cysts are very common; cartilage is rare. The presence of cartilage may indicate a somewhat later embryologic insult, perhaps extending into the 10th–24th wk.

Diagnosis.

The size and progression of this lesion during fetal life and early postnatal life are more important than the histologic picture. Cystic adenomatoid malformations can be diagnosed in utero by ultrasonography. In one series of 16 such cases, the diagnosis was almost always made at 21–23 wk of gestation (range, 18–36 wk). Polyhydramnios was common (25%). Lesions that cause progressive mediastinal shift and fetal hydrops are almost always fatal. Large lesions, by compressing adjacent lung, may produce pulmonary hypoplasia in nonaffected lobes (see Chapter 383.2). However, even lesions that appear large in early gestation may regress considerably or decrease in relative size and be associated with good pulmonary function in childhood.

Clinical Manifestations.

Patients who present in the newborn period or early infancy have respiratory distress, recurrent respiratory infection, and pneumothorax. The lesion may be confused with diaphragmatic hernia. Patients with smaller lesions are asymptomatic until mid childhood, when brief episodes of recurrent or persistent pulmonary infection or relatively acute chest pain occur. Breath sounds may be diminished with mediastinal shift away from the lesion on physical examination. Chest radiographs reveal a cystic mass, sometimes with mediastinal shift. Occasionally, an air-fluid level suggests a lung abscess.

Treatment.

Surgical excision of the affected lobe is indicated, because there is a reported increased incidence of primary pulmonary neoplasms in long-term survivors.

383.4 Pulmonary Sequestration

A pulmonary sequestration is a congenital anomaly of lung development and is defined as intrapulmonary or extrapulmonary, depending on location within the visceral pleura or without. These terms are preferred, rather than “intralobar” and “extralobar.” The majority of sequestrations are intrapulmonary.

Pathophysiology.

The lung tissue in a sequestration receives its arterial supply from the systemic arteries (commonly off the aorta) and returns its venous blood to the right side of the heart, usually through the inferior vena cava. As a result, the sequestration functions as a space-occupying lesion within the chest that does not function in gas exchange and does not contribute to left-to-right shunt. Most sequestrations do not have a communication with the airway, and thus do not contribute to dead space. Communication with the airway may occur as the result of rupture of infected material into an adjacent airway. In addition, collateral ventilation within intrapulmonary lesions via pores of Kohn may occur. Intralobar and extralobar sequestrations may arise through the same pathoembryologic mechanism as a remnant of a diverticular outgrowth of the esophagus. However, some propose that intralobar sequestration is an acquired lesion primarily caused by infection and inflammation, which leads to cystic changes and hypertrophy of a feeding systemic artery. This is consistent with the rarity of this lesion in autopsy series of newborns. Gastric or pancreatic tissue may be found within the sequestration. Cysts may also be present. Other congenital anomalies, including diaphragmatic hernia and

esophageal cysts, are not uncommon. Some believe that intralobar sequestration is often a manifestation of cystic adenomatoid malformation and have questioned the existence of intralobar sequestration as a separate entity.

Clinical Manifestations and Treatment.

Intrapulmonary sequestration is generally found in a lower lobe and does not have its own pleura. Patients usually present with infection. In older patients, hemoptysis is fairly common. A chest radiograph during a period when there is no active infection reveals a mass lesion; an air-fluid level may be present. During infection, the margins of the lesion may be blurred. There is no difference in the incidence of this lesion in each lung. Treatment is surgical removal of the lesion, a procedure that usually requires excision of the entire involved lobe. Segmental resection occasionally suffices.

Extrapulmonary sequestration is much more common in males and almost always involves the left lung. This lesion is enveloped by a pleural covering and is associated strongly with diaphragmatic hernia. Patients may also have other associated abnormalities, such as colonic duplication, vertebral abnormalities, and pulmonary hypoplasia. Many of these patients are asymptomatic when the mass is discovered by routine chest radiography performed for another reason. Other patients present with respiratory symptoms or heart failure. Surgical resection of the involved area is recommended. Subdiaphragmatic extrapulmonary sequestration may present as an abdominal

---

mass on prenatal ultrasonography. In addition, with the advent of prenatal ultrasonography, fetal pulmonary sequestrations have been shown to spontaneously regress.

Physical findings in patients with sequestration include an area of dullness to percussion and decreased breath sounds over the lesion. During infection, crackles may also be present. A continuous or purely systolic murmur may be heard over the back. If findings on routine chest radiographs are consistent with the diagnosis, other procedures are indicated before surgical intervention. Bronchography reveals a mass of intrathoracic tissue without connection to the airways. Ultrasonography can help rule out a diaphragmatic hernia. Surgical removal is recommended. Preoperative aortography can be done to confirm the diagnosis and to delineate the blood supply of the lesion. However, some now believe that Doppler ultrasonography and MRI are sufficient in most cases. Identifying the blood supply before surgery avoids inadvertently severing this systemic artery, an event that has accounted for much of the intraoperative mortality in the past.

383.5 Bronchogenic Cysts

Bronchogenic cysts arise from abnormal budding of the tracheal diverticulum of the foregut before the 16th wk of gestation and are originally lined with ciliated epithelium. They are most commonly found on the right and near a midline structure (e.g., trachea, esophagus, carina), but peripheral lower lobe and perihilar intrapulmonary cysts are not infrequent. Diagnosis may be precipitated by enlargement of the cyst, which causes symptoms by pressure on an adjacent airway. When the diagnosis is delayed until infection occurs, the ciliated epithelium may be lost, and accurate pathologic diagnosis is then impossible. Cysts are rarely demonstrable at birth. Later, some cysts become symptomatic by becoming infected or by enlarging in size and compromising the function of an adjacent airway. Fever, chest pain, and productive cough are the most common presenting symptoms. A chest radiograph reveals the cyst, which may contain an air-fluid level. Additional information can be obtained by CT scan or barium esophagography. Treatment of symptomatic cysts is surgical excision after appropriate antibiotic management. Even asymptomatic cysts discovered incidentally by chest roentgenogram taken for another reason should probably be treated by surgical excision, in view of the 75–90% rate of infection.

383.6 Congenital Pulmonary Lymphangiectasia

This disease, characterized by greatly dilated lymphatic ducts throughout the lung, can occur in several pathologic circumstances. Pulmonary venous obstruction produces an elevated transvascular pressure and engorges the pulmonary lymphatics. Generalized lymphangiectasis is a generalized disease of several organ systems, predominantly the intestines, and may affect the lungs, as well. Finally, lymphangiectasis may occur only in the lung.

Children with pulmonary venous obstruction or severe pulmonary lymphangiectasis present with dyspnea and cyanosis in the newborn period. Chest radiographs reveal diffuse, dense, reticular densities. If the lung is not completely involved, the spared areas appear hyperlucent. Respiration is compromised because of the space-occupying nature of the lesion and possibly because pulmonary compliance is reduced, increasing the work of breathing. The diagnosis can be made from right-sided heart catheterization, CT scans, and open lung biopsy. Treatment is only supportive and includes administration of oxygen, mechanical ventilation, and careful fluid management with diuretics. Primary pulmonary lymphangiectasia and pulmonary venous obstruction produce severe pulmonary dysfunction and are usually fatal in infancy. Occasionally, the pulmonary venous obstruction is secondary to left-sided cardiac lesions, and relief of the latter can produce improvement in pulmonary dysfunction. Generalized lymphangiectasis generally produces milder pulmonary dysfunction, and survival to mid childhood and beyond is not unusual.

383.7 Lung Hernia

A lung hernia is a protrusion of the lung beyond its normal thoracic boundaries. About 20% of instances of this disorder are congenital; the balance of cases are noted after chest trauma or thoracic surgery or in patients with pulmonary diseases such as cystic fibrosis and asthma, which cause frequent cough and generate high intrathoracic pressure. A congenital weakness of the suprapleural membranes or musculature of the neck may play a role in the appearance of a lung hernia. More than half of congenital lung hernias and almost all acquired hernias are cervical. Congenital cervical hernias usually occur anteriorly through a gap between the scalenus anterior and sternocleidomastoid muscles. Elsewhere, cervical herniation is prevented by the trapezius muscle (posteriorly, at the thoracic inlet) and the three

scalene muscles (laterally).

The presenting sign of a cervical hernia is usually a neck mass noticed while straining or coughing. Some lesions are asymptomatic and detected only when a chest film is taken for another reason. Findings on physical examination are normal except during Valsalva maneuver, when a soft bulge may be noticed in the neck. In most cases, no treatment is necessary. However, these hernias may cause problems during attempts to place a central venous catheter through the jugular or subclavian veins. Spontaneous resolution can occur.

Paravertebral or parasternal hernias are usually associated with rib anomalies. Intercostal hernias usually occur parasternally, where the external intercostal muscle is absent. Posteriorly, despite the seemingly inadequate internal intercostal muscle, the paraspinal muscles usually prevent herniation. Straining, coughing, or playing a musical instrument may have a role in causing intercostal hernias, but in most cases, there is probably a pre-existing defect in the thoracic wall.

Surgical treatment for lung hernia is occasionally justified for cosmetic reasons. In patients with severe chronic pulmonary disease and chronic cough and for whom cough suppression is contraindicated, permanent correction may not be achieved.

383.8 Other Congenital Malformations of the Lung

Congenital Lobar Emphysema and Pulmonary Cysts.

See Chapter 380 .

Pulmonary Arteriovenous Malformation.

See Chapter 425 and Chapter 436 .

Bronchobiliary Fistula.

This rare anomaly usually presents life-threatening problems during early infancy, but diagnosis occasionally has been delayed until adulthood. Females are more commonly affected. The bronchobiliary fistula consists of a fistulous connection between the right middle lobe bronchus and the left hepatic ductal system. All patients have recurrent severe bronchopulmonary infection starting in early infancy. Definitive diagnosis requires endoscopy and bronchography or exploratory surgery. Treatment includes surgical excision of the entire intrathoracic portion of the fistula. If the hepatic portion of the fistula does not communicate with the biliary system or duodenum, the involved segment may also have to be resected. Bronchobiliary communications also occur as

acquired lesions resulting from hepatic disease complicated by infection.

Chapter 384 - Pulmonary Edema

Robert Mazor
Thomas P. Green

Pulmonary edema is an excessive accumulation of fluid in the cells, interstitium, and air spaces of the lung. It is a common problem in the acutely ill child as a sequela of several different pathologic processes.

Pathophysiology.

The pressure and osmolarity on either side of a pulmonary capillary, as well as the capillary permeability, are the physical factors that determine fluid movement through the capillary wall. Baseline conditions lead to a net filtration of fluid from the intravascular space into the interstitium. This “extra” interstitial fluid is rapidly reabsorbed by pulmonary lymphatics. Conditions that lead to altered capillary permeability, increased pulmonary capillary pressure, or decreased intravascular oncotic pressure will increase the flow out of the capillary (Box 384–1) and thereby lead to water accumulation in the lung

To understand the sequence of lung water accumulation, it is helpful to consider its distribution among four distinct compartments.

1. *The vascular compartment:* This compartment consists of all blood vessels that participate in fluid exchange with the interstitium. The vascular compartment is separated from the interstitium by capillary endothelial cells. Several endogenous inflammatory mediators, as well as exogenous toxins, are implicated in the pathogenesis of pulmonary capillary endothelial damage, leading to the “leakiness” seen in several systemic processes.
2. *The interstitial compartment:* The importance of this space lies in its interposition between the alveolar and vascular compartments. As fluid leaves the vascular compartment it collects in the interstitium before overflowing into the air spaces of the alveolar compartment.
3. *The alveolar compartment:* This compartment is lined with type 1 and type 2 epithelial cells. A growing body of evidence exists outlining the role of these epithelial cells in active fluid transport from the alveolar space.
4. *The pulmonary lymphatic compartment:* There is an extensive network of pulmonary lymphatics. Excess fluid present within the alveolar and interstitial compartments is drained via the lymphatic system. When the capacity for

drainage of the lymphatics is surpassed, fluid accumulation occurs.

Box 384-1. Etiology of Pulmonary Edema

INCREASED PULMONARY CAPILLARY PRESSURE

- Cardiogenic, such as left ventricular failure
- Noncardiogenic, as in pulmonary veno-occlusive disease, pulmonary venous fibrosis, mediastinal tumors

INCREASED CAPILLARY PERMEABILITY

- Bacterial and viral pneumonia
- Acute respiratory distress syndrome (ARDS)
- Inhaled toxic agents
- Circulating toxins
- Vasoactive substances such as histamine, leukotrienes, thromboxanes
- Diffuse capillary leak syndrome, as in sepsis
- Immunologic reactions, such as transfusion reactions
- Smoke inhalation
- Aspiration pneumonia/pneumonitis
- Drowning and near-drowning
- Radiation pneumonia
- Uremia

- Drowning and near-drowning
- Radiation pneumonia
- Uremia

LYMPHATIC INSUFFICIENCY

- Congenital and acquired

DECREASED ONCOTIC PRESSURE

- Hypoalbuminemia, as in renal and hepatic diseases, protein-losing states, and malnutrition

INCREASED NEGATIVE INTERSTITIAL PRESSURE

- Upper airway obstructive lesions, such as croup and epiglottitis
- Re-expansion pulmonary edema

MIXED OR UNKNOWN CAUSES

- Neurogenic pulmonary edema
- High-altitude pulmonary edema
- Eclampsia
- Pancreatitis
- Pulmonary embolism
- Heroin (narcotic) pulmonary edema

Modified from Robin E, Carroll C, Zelis R: Pulmonary edema. N Engl J Med 1973; 288:239, 292 (2 parts) and Desphande J, Wetzel R, Rogers M: In Rogers M (editor): Textbook of Pediatric Intensive Care, 3rd ed. Baltimore, Williams & Wilkins, 1996, pp 432–42.

Etiology.

Box 384–1 lists the etiology of pulmonary edema. The specific clinical findings vary according to the underlying mechanism.

Increases in pulmonary vascular pressure *(capillary hydrostatic pressure)* lead to increased flow from the vessel. Cardiac processes that lead to failure of left-sided forward flow (e.g., myocarditis) or increased left-sided back flow (e.g., valvular regurgitation) increase pulmonary capillary pressure. In addition, there are noncardiac causes involving abnormalities of the pulmonary veins that obstruct venous drainage, leading to an increase in capillary pressure.

Increased capillary permeability is usually secondary to damage to the endothelium. Because of the large amount of pulmonary blood flow, the lung is especially susceptible to circulating

toxins. Endogenous substances such as inflammatory mediators (e.g., tumor necrosis factor-a, leukotrienes, thromboxanes) and vasoactive agents (e.g., nitric oxide, histamine) formed during pulmonary and systemic processes play a role in the endothelial damage, and, therefore, the altered capillary permeability that occurs with many disease processes.

Fluid homeostasis in the lung is dependent largely on drainage via the lymphatics. Experimentally, pulmonary edema occurs with obstruction of the lymphatic system. Increased lymph flow and dilation of lymphatic vessels occur in chronic edematous states.

By decreasing the forces promoting fluid re-entry into the vascular space, decreases in intravascular oncotic pressure lead to pulmonary edema. This occurs in dilutional disorders such as fluid overload with hypotonic solutions and in protein-losing states such as nephrotic syndrome and malnutrition.

Increased negative interstitial pressure is invoked in disorders in which upper airway obstruction exists, such as croup. Other mechanisms may also be involved. Theories implicate an increase in CO_2 tension, decreased O_2 tension, and extreme increases in cardiac afterload, leading to transient cardiac insufficiency.

The mechanism causing neurogenic pulmonary edema is not clear. A massive sympathetic discharge secondary to a cerebral insult may produce increased pulmonary and systemic vasoconstriction, resulting in a shift of blood to the pulmonary vasculature, an increase in capillary pressure, and edema formation. The mechanism causing high-altitude pulmonary edema is unclear, but it may also be related to sympathetic outflow, increased pulmonary vascular pressures, and hypoxia-induced increases in capillary permeability.

Clinical Manifestations.

The clinical features that arise depend on the mechanism of edema formation. In general, the interstitial and alveolar edema prevent the inflation of alveoli, leading to atelectasis and decreased surfactant production, resulting in decreased pulmonary compliance and decreased tidal volumes. In an effort to maintain adequate minute ventilation, the patient must increase respiratory effort to preserve tidal volume and/or increase respiratory rate. With the accumulation of fluid in the alveolar space, auscultation reveals fine crackles and wheezing, especially in dependent lung fields.

Chest radiographs can provide useful ancillary data. Early radiographic signs include peribronchial and perivascular cuffing representing accumulation of interstitial edema. Diffuse streakiness reflects interlobular edema and distended pulmonary lymphatics. Diffuse, patchy densities secondary to alveolar filling are a late sign. Cardiomegaly and increased pulmonary vascular markings are seen with causes involving left ventricular dysfunction. Chest tomography demonstrates that edema accumulates in the dependent areas of the lung. Therefore, changing the patient position can alter regional differences in lung compliance and alveolar ventilation.

Treatment.

The treatment of a patient with pulmonary edema should be directed toward the underlying cause. Patients should receive supplemental oxygen in an effort to increase alveolar oxygen tension and decrease pulmonary vasoconstriction. Patients with cardiogenic causes should be managed with inotropes, afterload-reducing agents, and diuretic agents. Several groups have questioned the universal use of diuretics in adults with pulmonary edema stating that the pulmonary edema is not, in general, associated with fluid retention but, rather, is associated with fluid redistribution. However, diuretics are valuable in the treatment of pulmonary edema associated with total-body fluid overload (e.g., sepsis, renal insufficiency). Morphine is often helpful as a vasodilator and a mild sedative.

Several studies have demonstrated the effectiveness of positive airway pressure such as positive end-expiratory pressure (PEEP) and continuous positive airway pressure (CPAP). The mechanism by which positive airway pressure improves pulmonary edema is not entirely clear but does not seem to be associated with decreasing lung water. Rather, CPAP prevents closure of alveoli and may reopen collapsed alveolar units. This leads to increased functional residual capacity (FRC). Increased FRC leads to improved pulmonary compliance, improved surfactant function, and decreased pulmonary vascular resistance. The net effect is to decrease the work of breathing, improve oxygenation, and decrease cardiac afterload.

Chapter 385 - Aspiration Syndromes

John L. Colombo

A child with aspiration of foreign materials into the lungs may present with obvious acute lung injury from massive or highly toxic substance aspiration, mechanical obstruction of large or intermediate-sized airways, infectious complications of aspiration, or recurrent microaspiration, such as may occur with gastroesophageal reflux or mild dysphagia. The first presentation listed is the focus of this chapter.

Occult aspiration of nasal pharyngeal secretions into the lower respiratory tract has been shown to be a normal event in healthy people, usually without apparent clinical significance. The spectrum of aspiration extends from this asymptomatic group to acute life-threatening events, such as with massive aspiration of gastric contents or hydrocarbon products. Most patients suffering with a syndrome of aspiration have disorders that lie between the ends of this spectrum and present a tremendous challenge in both diagnosis and treatment.

LARGE VOLUME OR TOXIC ASPIRATIONS

Gastric Contents.

Aspiration of large volumes most commonly occurs with aspiration after vomiting. The pathologic and physiologic consequences can vary depending on the pH and volume of the aspirate and the amount of particulate material. Increased clinical severity should be expected with volumes greater than approximately 0.8?mL/kg and/or pH less than 2.5. Hypoxemia, hemorrhagic pneumonitis, atelectasis, intravascular fluid shifts, and pulmonary edema all occur rapidly with massive aspiration. These will occur earlier, become more severe, and last longer with acid aspiration. Most clinical changes are present within minutes to 1–2?hr after aspiration. Over the next 24–48?hr there is a marked increase in lung parenchymal neutrophil infiltration, mucosal sloughing, and alveolar consolidation that often correlates with increasing infiltrates on chest radiographs. These changes tend to occur significantly later and are more prolonged after aspiration of small particles. Infection usually does not play a role in initial lung injury after aspiration of gastric contents. However, such aspiration may impair pulmonary defenses, predisposing to later secondary bacterial pneumonia.

Hydrocarbon Aspiration.

The most dangerous consequence of acute hydrocarbon ingestion is usually aspiration and resulting pneumonitis. Fortunately, significant pneumonitis is a relatively infrequent event, occurring in less than 2% of all hydrocarbon ingestions. However, the outcome can be severe. There are an estimated 20 deaths annually from hydrocarbon aspiration in both children and adults. Of these, several represent successful suicide attempts. Hydrocarbons with lower surface tensions (gasoline, turpentine, naphthalene) have more potential for aspiration toxicity than heavier mineral or fuel oils. Ingestion of more than 30?mL (approximate volume of an adult swallow) of hydrocarbon is associated with an increased risk of severe pneumonitis. Patients presenting with shortness of breath or hypoxemia are at high risk for severe pneumonitis. Other organ systems also may suffer serious injury, especially the liver, central nervous system, and heart. Cardiac dysrhythmias may occur and be exacerbated by hypoxia and acid-base or electrolyte disturbances.

Certain hydrocarbons have more inherent system toxicity. These are referred to collectively by the mnemonic CHAMP: *c*amphor, *h*alogenated hydrocarbons, *a*romatic hydrocarbons, and those associated with *m*etals and *p*esticides. Patients who ingestion these compounds in volumes greater than 30?mL, such as may occur especially with intentional overdose, may benefit from gastric emptying. However, as a general rule, gastric emptying is contraindicated because of further risk of aspiration. If gastric emptying is utilized, it must be done cautiously to avoid aspiration. If a cuffed endotracheal tube can be placed without inducing vomiting, this should be considered, especially in the presence of altered mental status. Treatment of each case should be considered individually with guidance from a poison control center.

Other substances that are particularly toxic and occasionally aspirated, causing significant lung injury, include baby powder, chlorine, shellac, beryllium, and mercury vapors. Repeated exposures to lower concentrations of these agents may lead to chronic lung disease, such as interstitial pneumonitis and granuloma formation. Corticosteroids may help reduce fibrosis development.

Treatment.

If the patient has an artificial airway it is important to perform immediate suctioning of the airway. However, bronchoscopy is usually of limited therapeutic value unless it can be performed very soon after massive aspiration, or significant particle aspiration is suspected. If bronchoscopy is performed, findings of localized carinal erythema and microscopic or macroscopic food particles may be helpful if the diagnosis is in doubt. Attempts at acid neutralization are not warranted because acid is neutralized by the respiratory epithelium very rapidly. Patients with potential massive aspiration or hydrocarbon aspiration should be observed, have oxygenation measured (by oximetry or blood gas analysis), and have a chest radiograph taken, even if asymptomatic. If the chest radiograph and oxygen saturation are normal, and the patient remains asymptomatic, the patient may usually be observed at home after an observation period in the hospital or office. No therapy at that time would be indicated, but the parents should be instructed to bring their child for medical attention if respiratory symptoms or fever develops.

For those patients with abnormal findings, oxygen therapy is necessary to correct hypoxemia. Endotracheal intubation and mechanical ventilation are often necessary for more severe cases. Bronchodilators may be given, although they are usually of limited benefit. Treatment with corticosteroids does not appear to have any benefit unless they can be given nearly simultaneously with the time of aspiration (based primarily on animal studies), and their use may increase the risk of secondary infection. As a general rule, prophylactic antibiotics are not indicated. However, risk-benefit must be assessed and, in the patient with very limited reserve, antibiotic coverage, especially for mixed anaerobes, may be appropriate. If the aspiration occurs in a hospitalized or chronically ill patient, coverage for *Pseudomonas* and enteric gram-negative organisms should also be considered. With massive aspiration, mortality rates as high as 40–80% have been reported. More recent reports indicate a mortality rate of 5%, and even lower if three or fewer lobes are involved. Unless complications develop, such as infection, most patients will recover in 2–3 wk, but prolonged lung damage may persist with scarring and bronchiolitis obliterans.

Feeding with enteral tubes passed beyond the pylorus and elevating the head of the bed of mechanically ventilated patients have been shown to reduce the incidence of aspiration complications.

Chapter 386 - Chronic Recurrent Aspiration

John L. Colombo

The recurrent aspiration of gastric, nasal, or oral contents can lead to several clinical presentations, including recurrent bronchitis or bronchiolitis, recurrent pneumonia, atelectasis, wheezing, cough, apnea, or laryngospasm. Pathologic outcomes include granulomatous inflammation, interstitial inflammation, fibrosis, lipoid pneumonia, and bronchiolitis obliterans. Underlying disorders that are frequently associated with recurrent aspiration are listed in Box 386–1 .

In a series of 238 children hospitalized with recurrent pneumonia, the most common underlying problem was oropharyngeal incoordination present in 48% of these patients. Gastroesophageal reflux (GER) is also a common underlying problem that may predispose to recurrent respiratory disease but is less commonly associated with recurrent pneumonia. GER is discussed in Chapter 387 (see also Chapter 304).

Clinical Manifestations and Diagnosis.

Underlying predisposing factors, such as those mentioned in Box 386–1 , although frequently obvious, sometimes may require further evaluation. Initial assessment begins with a detailed history and physical examination. The caregivers should be asked about the timing of symptoms in relation to feedings, positional changes, spitting, vomiting, arching, or epigastric discomfort in an older child and nocturnal symptoms with coughing or wheezing. Coughing or gagging may be minimal or absent in a child with a depressed cough or gag reflex. Observation of a feeding is essential when considering a diagnosis of recurrent aspiration. Particular attention should be given to nasopharyngeal reflux, difficulty with sucking or swallowing, and associated coughing and choking. Oral cavities should be inspected for gross abnormalities and

- Prolonged hospitalization
- Gastric outlet or intestinal obstruction
- Poor feeding techniques (bottle propping, overfeeding, inappropriate foods for toddlers)

stimulated to assess the gag reflex. Drooling or excessive accumulation of secretions in the mouth suggest dysphagia. Lung auscultation may reveal transient wheezes or crackles after feeding, particularly in the dependent lung segments.

Laboratory Findings.

A plain chest radiograph is the usual initial study for a child suspected of having recurrent aspiration. The classic findings of segmental or lobar infiltrates localized in dependent areas may be found, but there are a wide variety of radiographic findings. These findings include diffuse infiltrates, lobar infiltrates, bronchial wall thickening, hyperinflation, and normal findings. CT scans may show infiltrates with decreased attenuation suggestive of lipoid pneumonia. CT scans are not commonly indicated to establish a diagnosis of aspiration, but the diagnosis may be an incidental finding when such imaging is done for other reasons.

Numerous other tests are available for detecting aspiration or GER. A carefully performed barium esophagram is very useful in looking for anatomic abnormalities such as vascular ring, stricture, hiatal hernia, or tracheoesophageal fistula. It also yields qualitative information about esophageal motility and, when extended, of gastric emptying. However, the esophagogram is quite insensitive and nonspecific

for aspiration or GER. A modified barium swallow with videofluoroscopy is generally considered the gold standard for evaluating the swallowing mechanism. The study is preferably done with assistance of a pediatric feeding specialist and a parent. The child should be seated in a normal eating position, and various consistencies of barium or barium-impregnated foods are offered. This is significantly more sensitive for demonstrating aspiration than bedside assessment or traditional barium swallow. The sensitivity of this modified barium swallow is such that it occasionally detects aspiration in patients without abnormal respiratory findings.

A gastroesophageal (“milk”) scintiscan offers theoretical advantages of being more physiologic and giving a longer window of viewing than the barium esophagram for detecting GER and aspiration. However, in most studies this has been relatively insensitive for detection of aspiration. Another radionuclide scan termed the *salivagram* is also useful to assess aspiration of oropharyngeal contents. The fiberoptic endoscopic evaluation of swallowing has been used primarily in adult patients but may have some utility in pediatric patients, especially when combined with laryngopharyngeal sensory testing.

Tracheobronchial aspirates also can be examined for numerous entities to evaluate for aspiration. For patients with artificial airways, the use of an oral dye and visual examination of tracheal secretions is commonly used. This test should not be done on a chronic basis owing to possible dye toxicity. In using this test acutely, it is important to administer an adequate volume of dye, but even this may be relatively insensitive compared with measuring lactose or glucose in appropriately fed patients. Quantitation of lipid-laden alveolar macrophages from bronchial aspirates is a sensitive and relatively specific test for lipid aspiration, but false-positive tests undoubtedly occur, especially with endobronchial obstruction and use of intravenous lipids. Bronchial washings may also be examined for various food substances, including lactose, glucose, food fibers, and milk antigens. Specificity and sensitivity of these tests have not been well delineated.

Treatment.

If chronic aspiration is associated with another underlying medical condition, treatment should be directed toward that problem. The frequency and severity of respiratory problems will determine the level of intervention. Often mild dysphagia can be treated with alteration of feeding position or giving thickened foods. Nasogastric tube feedings can be utilized temporarily during periods of transient vocal cord dysfunction or other dysphagia. Postpyloric feedings may also be helpful, especially when GER is a concern.

Several surgical procedures may be considered. Tracheostomy, although sometimes actually predisposing to aspiration, may provide overall benefit from improved bronchial hygiene. Fundoplication with a gastrostomy or jejunostomy feeding tube will reduce the probability of GER-induced disease, but recurrent pneumonias often persist because of dysphagia and presumed aspiration of upper airway secretions. Medical treatment with anticholinergics, such as glycopyrrolate, may significantly reduce salivation and morbidity from salivary aspiration but often has side effects. Aggressive surgical intervention with salivary gland excision, ductal ligation, or laryngotracheal separation may be considered in severe, unresponsive cases. Surgical therapy usually is reserved for the most severe cases but may be associated with significant improvement of quality of life.

Chapter 387 - Gastroesophageal Reflux and Respiratory Disorders

John L. Colombo

Over 50% of children with chronic asthma and/or recurrent pneumonia also have excessive gastroesophageal reflux (GER). In addition to these disorders, GER has been associated with apnea (both central and obstructive), stridor, and recurrent cough. It also is found to an excess degree in bronchopulmonary dysplasia and cystic fibrosis. Although respiratory disease can induce GER by increasing abdominothoracic pressure gradients, there is substantial evidence suggesting that the more common pathway is that for GER to trigger respiratory symptoms, particularly of asthma. This may occur from microaspiration with resultant direct inflammation and bronchoconstriction, from vagally mediated effects from stimulation of upper airway receptors, or from esophageal afferent irritation causing a neurogenic reflex.

Clinical Manifestations and Diagnosis.

The initial diagnostic approach follows that outlined in Chapter 386 for chronic, recurrent aspiration. It is not always possible to ascertain whether a patient is having microaspiration with GER, and it is often easier to demonstrate GER than aspiration. Barium esophagogram may be warranted with the same caveats noted in Chapter 386 . Esophageal pH monitoring is widely considered the gold standard for detecting GER. This test is discussed in Chapter 304 , but it should be mentioned here that the definition of pathologic GER used by gastroenterologists may be very different than that which is necessary to provoke respiratory disease. In susceptible individuals, even a normal degree of acid GER may cause respiratory illness, although esophagitis would not be expected. Post-prandial, non-acid GER also will not be detected. Because of this, as well as lack of strong criteria for determining which children with respiratory disease should be evaluated for GER, and given cost-efficacy considerations, an empirical diagnostic/therapeutic trial of anti-GER therapy is often warranted.

Treatment.

See Chapter 304 . However, control of GER does not necessarily alleviate respiratory symptoms, especially in children with neurologic impairment. This likely relates to the additional problems of these children who have poor airway protection, dysphagia, and aspirate oral contents.

Chapter 388 - Parenchymal Disease with Prominent Hypersensitivity, Eosinophilic Infiltration, or Toxin-Mediated Injury

Oren Lakser

388.1 Hypersensitivity to Inhaled Materials

Hypersensitivity pneumonitis (HP) or extrinsic allergic alveolitis is an immunologically mediated diffuse inflammatory disease of the pulmonary interstitium caused by inhalation of a variety of organic antigens. Usually these antigens are of animal or vegetable origin and are typically between 1–5?µm and therefore deposit in the alveoli. Reactive antigens, such as a variety of drugs, can occasionally cause HP.

Etiology.

Although typically an adult disease, HP has been reported in children and even infants. There are many types of HP related to the offending antigen. The most common forms in the United States include *farmer's lung* (from moldy hay; antigen is thermophilic actinomycetes), *bird fancier's* or *breeder's lung* (from feces or urine of a wide variety of species), and *ventilation* or *humidifier HP* (from contaminated humidifiers or air conditioners; also caused by thermophilic actinomycetes). Most case reports of HP in children have been the result of antigens inhaled during avian exposure or exposure to molds. There has been one report of HP after exposure to cat hair antigen.

Pathology and Pathogenesis.

HP can present as an acute, subacute, or chronic illness. These forms can be distinguished based on the morphologic features of the pulmonary involvement. In the *acute* stage, alveolar walls are infiltrated with neutrophils, lymphocytes, plasma cells, and macrophages. The alveolar lumen may contain a proteinaceous exudate mixed with inflammatory cells. Repeated or continuous exposure may result in a *subacute* presentation. This stage is characterized by the classic noncaseating granuloma associated with HP. Often, there is an associated terminal and respiratory bronchiolitis and alveoli may have pale foamy macrophages. The *chronic* form demonstrates further progression of the granulomatous alveolitis resulting in interstitial fibrosis and honeycombing, primarily affecting the upper lobes.

The immune mechanisms involved with inducing these morphologic changes may include immune complex (type III) hypersensitivity (particularly in the acute presentation), delayed cellular (type IV) hypersensitivity, and the alternate complement pathway.

Clinical Manifestations.

Acute attacks generally occur 4–8?hr after an exposure. Typical symptoms include fever, chills, cough, dyspnea, myalgia, and malaise that can persist for up to 48?hr. Physical examination usually reveals an ill-appearing, dyspneic child with bibasilar crackles or normal lung examination. Chest radiographs may also be normal or may demonstrate bilateral ground-glass haziness, often sparing the lung apices and bases. These patients may progress to the *subacute* presentation if exposure continues or recurs. The cough worsens, dyspnea becomes more prominent, and anorexia and weight loss may occur. The chest radiograph at this stage takes on a more reticulonodular appearance. Long-term exposure can lead to the *chronic* presentation. Dyspnea and cough are severe, with weight loss, weakness,

and hypoxemia. These patients eventually develop chronic alveolitis and fibrosis that can lead to cor pulmonale. Chest radiographs show coarse reticulonodular infiltrates and bronchiectasis primarily in the upper and mid-lung zones.

Diagnosis.

The diagnosis of HP is based primarily on the clinical presentation in association with a suspicious exposure. Because the clinical presentation is nonspecific, a high index of suspicion is crucial. A number of laboratory tests may be helpful in confirming a clinical suspicion. HP patients often demonstrate a modest leukocytosis with neutrophilia and a left shift and modest elevation of the erythrocyte sedimentation rate. Serum levels of immunoglobulins (IgG, IgM, and IgA) are often elevated. Skin testing to particular antigens lacks sensitivity and specificity, as do serum precipitins to specific antigens. Both these tests may indicate exposure, but without disease. Bronchoalveolar lavage (BAL) fluid typically demonstrates a marked lymphocytosis (often up to 70%) particularly of the $CD8^+$ suppressor T-cells. BAL fluid may also contain higher levels of immunoglobulins. Pulmonary function tests classically demonstrate a restrictive pattern with impaired gas exchange (diffusion capacity). The presence of a mild obstructive pattern during the acute stage is a poor prognostic indicator. Lastly, some have advocated an inhalational challenge either in the laboratory or by re-exposure to the environment. Challenge testing can be dangerous and therefore should be undertaken only in appropriately equipped diagnostic centers.

Treatment.

The single most effective therapeutic approach is complete avoidance of the

suspected antigen. Corticosteroids (1–2?mg/kg/24?hr) are of some benefit, but an extended course, perhaps up to 6 mo, is required. In general, prognosis is quite good, but if exposure persists, pulmonary fibrosis may occur and patients may not completely recover their baseline lung function.

388.2 Silo Filler Disease

Silo filler disease is also known as silage gas poisoning, or silo filler pneumoconiosis, and is typically caused by nitrogen dioxide toxicity. Nitrogen dioxide is produced in silos (particularly corn silos) within a few hours of filling and reaches a maximum concentration within about 2 days. Dangerous concentrations of gas can remain in a closed silo for as long as 2 wk.

Clinical Manifestations and Diagnosis.

Cough and dyspnea typically occur immediately on entering the silo and are often associated with wheezing, nausea, a choking sensation, and fatigue. Rarely, symptoms may be delayed days or even weeks after exposure. Radiologic manifestations include pulmonary edema in the perihilar areas and bases. Some patients may recover and the pulmonary edema clears rapidly. However, often this initial phase is followed by a period of remission for 2–3 wk. This quiescent period gives way to a second phase characterized by fever, progressive dyspnea, cyanosis, and cough associated with widespread, scattered miliary opacities that could become confluent and take on a more patchy and nodular appearance. These patients may suffer from methemoglobinemia.

Biopsy or autopsy findings include diffuse pulmonary edema, hyperplastic airway epithelium, widened intralobular septa, and bronchiolitis obliterans.

Treatment.

Although no controlled trial has been conducted, high-dose corticosteroids have been reported to be of some benefit in reducing the severity and duration of the symptoms. Bronchodilators may also be of some limited benefit. Methemoglobinemia is treated with methylene blue in severe cases. Silo filler disease may be fatal, result in complete recovery, or leave patients with chronic lung disease associated with fibrosis and emphysema.

388.3 Paraquat Lung

Paraquat is the most toxic dipyridilium herbicide. Concentrated solutions (12–20%) tend to be more dangerous than dilute solutions. Its toxic effects result from the production of superoxides and other highly reactive free radicals that cause the peroxidation of cell membranes and selective mitochondrial damage, resulting in cell death. Paraquat selectively concentrates in the lungs because of an amine uptake process that exists in alveolar epithelial cells. Additionally, paraquat-induced injury is significantly increased in the presence of high concentrations of oxygen.

Pathophysiologically, there is direct injury to the alveolar-capillary membrane and surfactant loss, adult respiratory distress syndrome, progressive intra-alveolar pulmonary fibrosis, and respiratory failure.

Clinical Manifestations.

There are three degrees of paraquat intoxication that appear to be dose related. Patients with mild poisoning after ingestion of less than 20?mg of paraquat ion/kg body weight are usually asymptomatic or may develop vomiting, diarrhea, and mild impairment of gas exchange. Moderate to severe poisoning follows ingestion of 20–40?mg of paraquat ion/kg. These patients typically suffer from vomiting, diarrhea, and caustic injury to the oral or esophageal mucosa and may develop renal failure, hepatic dysfunction, and progressive pulmonary fibrosis, resulting in respiratory failure and death. Acute fulminant poisoning follows ingestion of more than 40?mg of paraquat ion/kg. Marked ulceration of the oropharynx and esophagus occurs, with

multiorgan failure and 100% mortality within hours of ingestion.

Treatment.

Treatment is generally supportive because no antidote exists. Gastric lavage, activated charcoal, hemoperfusion, and hemodialysis are of limited value in significant poisoning. There have been rare individual case reports of successful treatment of paraquat poisoning with antioxidant therapy consisting of deferoxamine infusion and acetylcysteine. In general, results from lung transplantation are dismal, likely related to long-term storage of paraquat in muscle and eventual reaccumulation in the transplanted lungs. One patient survived transplant when the transplant was delayed more than 40 days after the ingestion.

Overall prognosis is poor. Survivors generally suffer from a persistent restrictive defect with impaired diffusion capacity on tests of pulmonary function.

388.4 Eosinophilic Lung Disease (Formerly Löffler Syndrome)

Eosinophilic lung diseases are a heterogeneous group of disorders linked by the common findings of pulmonary infiltrates and circulating or tissue eosinophilia. Recently, many have adopted the term *pulmonary infiltrates with eosinophilia* (PIE) as better terminology for these disorders. There are numerous classification schemes for these types of lung disease. In general, PIE syndromes can be divided into simple pulmonary eosinophilia (Löffler syndrome), prolonged pulmonary eosinophilia, tropical pulmonary eosinophilia, pulmonary eosinophilia with asthma, polyarteritis nodosa, chronic eosinophilic pneumonia, and acute eosinophilic pneumonia. Others have included **Churg-Strauss syndrome**, allergic bronchopulmonary aspergillosis (ABPA), and idiopathic hypereosinophilia syndrome. Other lung diseases such as idiopathic pulmonary fibrosis, Langerhan cell granuloma, and other interstitial lung diseases may have associated eosinophilia but are better classified elsewhere.

Löffler syndrome, the most common PIE syndrome reported in children, is characterized by migrating pulmonary infiltrates accompanied by peripheral blood eosinophilia but minimal respiratory symptoms. This term is rarely used today, and it is likely that most patients with this diagnosis have allergic bronchopulmonary helminthiasis (parasites), medication reactions, or ABPA.

Epidemiology.

PIE syndromes appear to be much less common in the pediatric population than in adults. There have been scattered case reports of acute eosinophilic pneumonia and chronic eosinophilic pneumonia in children. However, children previously classified as having Löffler syndrome make up the majority of pediatric cases. Most pediatric case reports suggest an equal number of males and females being affected; however, there may be geographic differences because one group reports a female preponderance in children, similar to adult patients with PIE syndromes. Age at presentation ranges from infancy to adolescence.

Pathology and Pathogenesis.

In the pediatric population the most common etiology of PIE syndromes includes parasite infections and drug reactions. The prevalence of individual parasite infections varies geographically. The most common parasite causing PIE syndromes in the United States is *Ascaris lumbricoides*. The eggs are ingested. After the larva hatch, they pass through the intestinal wall and migrate to the lungs, causing an intense inflammatory reaction. Alveolar macrophages, lymphocytes, neutrophils, and eosinophils are the most striking inflammatory cells. Other common parasites include *Strongyloides* species, *Toxocara canis* (dog roundworm, visceral larva migrans), and *Ancylostoma braziliense* ("creeping eruption"). In Africa, South America, and Southeast Asia the filarial worms *Wuchereria bancrofti* and *Brugia malayi* cause tropical pulmonary eosinophilia.

Several drugs have also been reported to cause PIE syndromes. Sulfasalazine, penicillin, ampicillin, ibuprofen, and cromolyn are a few of these drugs that are of common use in pediatric patients. Immunologic mechanisms may be the means by which these drugs result in an intense pulmonary inflammatory reaction.

Clinical Manifestations.

In general, patients with PIE syndromes caused by *parasites* or *drugs* present with chronic cough, intermittent fevers, dyspnea, wheezing, and occasionally abdominal pain and weight loss. Symptom duration varies. In *acute eosinophilic pneumonia,* symptoms are usually present for less than a month. In *chronic eosinophilic pneumonia,* symptoms are present for more than 6 mo. Results of physical examination vary but often show tachypnea, crackles, and wheezing.

Diagnosis.

The diagnosis of a PIE syndrome is made by clinical manifestations with associated

blood eosinophilia and chest radiographic findings. Radiologically, these patients present with nonspecific interstitial, alveolar, or mixed infiltrates. The infiltrates tend to be bilateral and diffuse. Patients with chronic eosinophilic pneumonia demonstrate peripheral infiltrates with central sparing (“photographic negative of pulmonary edema”). In addition, eosinophilic lung diseases can be diagnosed by the presence of pulmonary infiltrates and eosinophilia on bronchoalveolar lavage. Lastly, lung biopsy can be used to make the diagnosis.

Treatment.

Therapy varies with the type of PIE syndrome. In general, parasite and drug-induced PIE syndromes carry a good prognosis and resolve spontaneously with supportive care and removal of exposure. Rarely, medications to eradicate the parasites may be warranted. Patients with other forms of eosinophilic lung diseases including acute eosinophilic pneumonia and chronic eosinophilic pneumonia may require a course of corticosteroids. Prognosis for patients with most forms of eosinophilic lung disease is good. Acute eosinophilic pneumonia, however, may be life threatening.

Chapter 389 - Pneumonia

Theodore C. Sectish
Charles G. Prober

Pneumonia is an inflammation of the parenchyma of the lungs. Most cases of pneumonia are caused by microorganisms, but there are several noninfectious causes, which include but are not limited to aspiration of food or gastric acid, foreign bodies, hydrocarbons, and lipoid substances; hypersensitivity reactions; and drug- or radiation-induced pneumonitis. Infections in neonates (see Chapter 98) and other immunocompromised hosts (see Chapter 164) are distinct from infections occurring in otherwise normal infants and children.

Pneumonia is a significant cause of mortality in childhood throughout the world, particularly in developing countries. It causes approximately 4 million deaths among children worldwide. In the United States from 1939 to 1996, mortality caused by pneumonia in children declined by 97%. It is hypothesized that this decline is attributable to the introduction of antibiotics and the expansion of medical insurance coverage for children

Etiology.

The cause of pneumonia in an individual patient is often difficult to determine because direct culture is invasive

and usually not indicated. Bacterial and viral causes are found in 44–85% of children with community-acquired pneumonia, with more than one pathogen in 25–40%. The most common combination of pathogens is *Streptococcus pneumoniae* (pneumococcus) with either respiratory syncytial virus (RSV) or *Mycoplasma pneumoniae.*

Specific risk factors for the development of pneumonia include (1) lung disease, such as asthma or cystic fibrosis; (2) anatomic problems, such as tracheoesophageal fistula; (3) gastroesophageal reflux disease with aspiration; (4) neurologic disorders that interfere with protection of the airway or compromise clearing of the airway; and

(5) diseases that alter the immune system, such as immunodeficiency diseases or hemoglobinopathies.

Epidemiology.

Epidemiologic factors are useful in determining the etiology of pneumonia. Age, season of the year, immunization status, and health status of the child are helpful in narrowing the list of possible causes. Viral pathogens are the predominant cause of lower respiratory tract infections in infants and children younger than 5 yr of age. Unlike bronchiolitis, for which the peak attack rate is within the 1st yr of life, the peak attack rate for viral pneumonia is between the ages of 2 and 3 yr and decreases slowly thereafter.

Of the respiratory viruses, RSV is the major pathogen, especially in children younger than 3 yr of age. Other common viruses causing pneumonia include parainfluenza viruses, influenza viruses, and adenoviruses. Nonviral pathogens including *S. pneumoniae, M. pneumoniae*, and *Chlamydia pneumoniae* are more common in children older than 5 yr of age. Other bacterial causes of pneumonia in normal children are group A *Streptococcus* (*Streptococcus pyogenes*) and *Staphylococcus aureus. Haemophilus influenzae* type b was an important cause of bacterial pneumonia in young children in the past but has become uncommon with the routine use of effective vaccines. Similarly, the overall incidence of disease caused by *S. pneumoniae* should decline with the introduction of the heptavalent conjugated pneumococcal vaccine. For example, in one study conducted in a daycare center in Israel, there was a 16% reduction in the incidence of lower respiratory tract infections in vaccine recipients.

Lower respiratory tract viral infections in the United States are much more common in the fall and winter, related to the seasonal epidemics of respiratory viral infection that occur each year. The typical pattern of these epidemics usually begins in the fall when parainfluenza infections appear and are most often manifest as croup. Later in winter, RSV and influenza virus cause widespread infection, including upper respiratory tract infections, bronchiolitis, and pneumonia. RSV attacks infants and young children, whereas influenza virus causes disease and excess hospitalization for acute respiratory illness in all age groups. The knowledge of the prevailing viral epidemic may lead to a presumptive initial diagnosis.

Immunization status is relevant because children fully immunized against *H. influenzae* type b and *S. pneumoniae* are less likely to be infected with these pathogens. Children who are immunosuppressed or who have an underlying illness are at risk for specific pathogens, such as *Pseudomonas* in patients with cystic fibrosis.

Pathogenesis.

The lower respiratory tract is normally kept sterile by physiologic defense mechanisms, including the mucociliary escalator, the properties of normal secretions such as secretory IgA, and clearing of the airway by coughing. Immunologic defense mechanisms of the lung that limit invasion by pathogenic organisms include macrophages that are present in alveoli and bronchioles, secretory IgA, and other immunoglobulins.

Viral pneumonia usually results from spread of infection along the airways, accompanied by direct injury of the respiratory epithelium resulting in airway obstruction from swelling, abnormal secretions, and cellular debris. The small caliber of airways in young infants makes them particularly susceptible to severe infection. Atelectasis, interstitial edema, and ventilation-perfusion mismatch causing significant hypoxemia often accompany airway obstruction. Viral infection of the respiratory tract also can predispose to secondary bacterial infection by disturbing normal host defense mechanisms, altering secretions, and modifying the bacterial flora.

When bacterial infection is established in the lung parenchyma, the pathologic process varies according to the invading organism. *M. pneumoniae* attaches to the respiratory epithelium, inhibits ciliary action, and leads to cellular destruction and an inflammatory response in the submucosa. As the infection progresses, sloughed cellular debris, inflammatory cells, and mucus cause airway obstruction, with spread of infection occurring along the bronchial tree similar to that of viral pneumonia.

S. pneumoniae produces local edema that aids in the proliferation of organisms and spread into adjacent portions of lung, often resulting in the characteristic focal lobar involvement.

Group A *Streptococcus* infection of the lower respiratory tract results in more diffuse infection with interstitial pneumonia. The pathology includes necrosis of tracheobronchial mucosa; formation of large amounts of exudate, edema, and local hemorrhage with extension into the interalveolar septa; and involvement of lymphatic vessels and the increased likelihood of pleural involvement.

S. aureus pneumonia is manifest by confluent bronchopneumonia, which is often unilateral and characterized by the presence of extensive areas of hemorrhagic necrosis and irregular areas of cavitation of the lung parenchyma, resulting in pneumatoceles, empyema, or, at times, bronchopulmonary fistulas.

An underlying disorder should be considered if a child experiences recurrent bacterial pneumonia. Defects to consider include abnormalities of antibody production (e.g., agammaglobulinemia, hypogammaglobulinemia, or IgG subclass deficiencies), granulocyte defects (e.g., chronic granulomatous disease), cystic fibrosis, ciliary dyskinesia, congenital bronchiectasis, tracheoesophageal fistula, increased pulmonary blood flow, or a deficient gag reflex. Additional factors that promote pulmonary infection include trauma, anesthesia, and aspiration.

Clinical Manifestations.

Viral and bacterial pneumonias are most often preceded by several days of symptoms of an upper respiratory tract infection, typically rhinitis and cough. In viral pneumonia, fever usually is present; however, temperatures are generally lower than in bacterial pneumonia. Tachypnea is the most consistent clinical manifestation of pneumonia. Increased work of breathing accompanied by intercostal, subcostal, and suprasternal retractions, nasal flaring, and use of accessory muscles is common. Severe infection may be accompanied by cyanosis and respiratory fatigue, especially in infants. Auscultation of the chest may reveal crackles and wheezing, but it often is

difficult to localize the source of these adventitious sounds in very young children with hyperresonant chests. It is difficult to clinically distinguish viral pneumonia from disease caused by *Mycoplasma* and other bacterial pathogens.

Bacterial pneumonia in adults and older children typically begins suddenly with a shaking chill followed by a high fever, cough, and chest pain. In older children and adolescents, a brief upper respiratory tract illness is followed by the abrupt onset of shaking chills and high fever accompanied by drowsiness with intermittent periods of restlessness; rapid respirations; a dry, hacking, unproductive cough; anxiety; and occasionally delirium. Circumoral cyanosis may be observed. Many children are noted to be splinting on the affected side to minimize pleuritic pain and improve ventilation; they may lie on their side with their knees drawn up to their chest.

Physical findings depend on the stage of pneumonia. Early in the course of illness, diminished breath sounds, scattered crackles, and rhonchi are commonly heard over the affected lung field. With the development of increasing consolidation or

complications of pneumonia such as effusion, empyema, or pyopneumothorax, dullness on percussion is noted and breath sounds are markedly diminished. A lag in respiratory excursion often occurs on the affected side. Abdominal distention may be prominent because of gastric dilation from swallowed air or ileus. The liver may seem enlarged because of downward displacement of the diaphragm secondary to hyperinflation of the lungs or superimposed congestive heart failure. Nuchal rigidity, in the absence of meningitis, may also be prominent, especially with involvement of the right upper lobe.

Symptoms described in adults with pneumococcal pneumonia may be noted in older children but are rarely observed in infants and young children, in whom the clinical pattern is considerably more variable. In infants, there may be a prodrome of upper respiratory tract infection and diminished appetite leading to the abrupt onset of fever, restlessness, apprehension, and respiratory distress. These infants appear ill with respiratory distress manifest by grunting; nasal flaring; retractions of the supraclavicular, intercostal, and subcostal areas; tachypnea; tachycardia; air hunger; and often cyanosis. Results of physical examination may, however, be misleading, particularly in young infants, with meager findings disproportionate to the degree of tachypnea. Some infants with bacterial pneumonia may have associated gastrointestinal disturbances characterized by vomiting, anorexia, diarrhea, and abdominal distention secondary to a paralytic ileus. Rapid progression of symptoms is characteristic in the most severe cases of bacterial pneumonia.

Diagnosis.

The chest radiograph confirms the diagnosis of pneumonia and may indicate a complication such as a pleural effusion or empyema. In general, viral pneumonia is characterized by hyperinflation with bilateral interstitial infiltrates and peribronchial cuffing (Fig. 389–1). Confluent lobar consolidation is typically seen with pneumococcal pneumonia (Fig. 389–2). However, the radiographic appearance alone is not diagnostic and other clinical features must be considered.

The peripheral white blood cell (WBC) count may be useful in differentiating viral from bacterial pneumonia. In viral pneumonia, the WBC count may be normal or elevated but usually not higher than 20,000/mm^3 with a lymphocyte predominance. Bacterial pneumonia is often associated with an elevated WBC count in the range of 15,000–40,000/mm^3 and a predominance of granulocytes.

The definitive diagnosis of a viral infection rests on the isolation of a virus or detection of viral antigens in respiratory tract secretions. Growth of respiratory viruses in tissue culture usually requires 5–10 days. Reliable reagents for the rapid detection of RSV, parainfluenza, influenza, and adenoviruses are available. Serologic techniques also can be used to diagnose a recent respiratory viral infection but generally require testing of acute and convalescent serum samples for a rise in antibodies to a specific viral agent. This diagnostic technique is laborious, slow, and not generally

Figure 389-1 *A*, Radiographic findings characteristic of RSV pneumonia in a 6-mo-old infant with rapid respirations and fever. Anteroposterior (AP) radiograph of the chest shows hyperexpansion of the lungs with bilateral fine air space disease and streaks of density, indicating the presence of both pneumonia and atelectasis. An endotracheal tube is in place. *B*, One day later the AP radiograph of the chest shows increased bilateral pneumonia.

clinically useful because the infection usually resolves by the time it is confirmed serologically. Nevertheless, serologic testing may be valuable as an epidemiologic tool to define the incidence and prevalence of the various respiratory viral pathogens.

The definitive diagnosis of a bacterial infection requires isolation of an organism from the blood, pleural fluid, or lung. Culture of sputum is of no value in the diagnosis of pneumonia in children. Blood cultures are positive in only 10–30% of children with pneumococcal pneumonia. In *M. pneumoniae* infections, cold agglutinins at titers greater than 1:64 are found in the blood in about 50% of patients. However, cold agglutinins are nonspecific because other infections such as influenza may also cause increases. Serologic evidence such as the anti–streptolysin O (ASO) titer is useful in the diagnosis of group A streptococcal pneumonia.

Treatment.

Treatment of suspected bacterial pneumonia is based on the presumptive cause and the clinical appearance of the child. For mildly ill children who do not require hospitalization, amoxicillin is recommended. In communities with a high percentage of penicillin-resistant pneumococci, high doses of amoxicillin (80–90?mg/kg/24?hr) should be prescribed. Therapeutic alternatives include cefuroxime axetil or amoxicillin/clavulanate. For school-aged children and in those in whom infection with *M. pneumoniae* is suggested, a macrolide antibiotic such as azithromycin is an appropriate therapeutic choice.

The empirical treatment of suspected bacterial pneumonia in a hospitalized child requires an approach based on the clinical manifestations at the time of presentation. Parenteral cefuroxime (75–150?mg/kg/24?hr) is the mainstay of therapy when bacterial pneumonia is suggested. If features suggest staphylococcal

pneumonia (e.g., pneumatoceles, empyema), initial therapy should also include vancomycin or clindamycin.

If viral pneumonia is suggested, it is reasonable to withhold antibiotic therapy. However, this option should be reserved for those patients who are mildly ill, have clinical evidence suggesting viral infection, and are in no respiratory distress. Up to 30% of patients with known viral infection may have co-existing bacterial pathogens; therefore, if the decision is made to withhold antibiotic therapy based on presumptive diagnosis of a viral infection, deterioration in clinical status should signal the possibility of superimposed bacterial infection and antibiotic therapy should be initiated.

Complications.

Complications of pneumonia are usually the result of direct spread of bacterial infection within the thoracic cavity (e.g., pleural effusion, empyema, and pericarditis) or bacteremia and hematologic spread. Meningitis, suppurative arthritis, and osteomyelitis are rare complications of hematologic spread of infection.

S. aureus and *S. pneumoniae* are the most common causes of empyema. The treatment of empyema is based on the stage (e.g., exudative, fibrinopurulent, or organizing). Imaging studies including ultrasonography and CT are helpful in determining

Figure 389-2 Radiographic findings characteristic of pneumococcal pneumonia in a 14-yr-old boy with cough and fever. Posteroanterior (*A*) and lateral (*B*) chest radiographs reveal consolidation in the right lower lobe, strongly suggesting bacterial pneumonia.

the stage of empyema. The mainstays of therapy include antibiotic therapy and drainage with tube thoracostomy. Newer approaches also include the use of fibrinolytic therapy and selected thoracoscopy to debride, lyse adhesions, and drain loculated areas of pus. Early diagnosis and intervention may obviate the need for thoracotomy and open debridement.

Chapter 390 - Slowly Resolving Pneumonia

Oren Lakser

Slowly resolving pneumonia refers to persistence of symptoms or radiographic abnormalities beyond the expected time course. The time course, however, will vary, depending on the organism involved, the extent of disease, and the presence of associated complicating conditions, such as pleural effusion, empyema, or lung abscess. In this chapter the focus is on the approach to the patient with delayed resolution of pneumonia; pneumonia is covered in Chapter 389 .

Typically, patients with uncomplicated community acquired bacterial pneumonia respond to therapy with improvement in clinical symptoms (e.g., fever, cough, dyspnea, chest pain) within 48–96?hr of initiation of antibiotics. Changes in empirical antibiotic therapy should be delayed for 2–4 days, unless the patient's condition worsens. In general, there should be radiographic evidence of improvement within 4–6 wk, but time to complete resolution varies depending on the etiologic organism. *Pneumococcal* pneumonias often require 1–3 mo for complete radiographic clearing. Similarly, chlamydial pneumonia can require 1–3 mo for complete resolution radiographically. *Mycoplasma pneumoniae* tends to clear more rapidly, with radiographic improvement occurring within 2 wk to 2 mo. Conversely, staphylococcal, *Legionella*, and enteric gram-negative pneumonias can take as long as 3–6 mo to resolve radiographically. Children with *viral* pneumonia may have positive radiographic findings for many months.

A number of factors must be considered when confronted with a patient with slowly resolving pneumonia. *Inadequate therapy* due to inappropriate antibiotic choice, inappropriate dose, or poor compliance is a common cause for slow or lack of improvement. In addition, the development of *resistant* organisms or *impaired host defenses* (immunodeficiencies, ciliary dyskinesia, or other co-existing illnesses) often results in a slower than expected time course for resolution. The possibility of a *nonbacterial* cause for the pneumonia should also be considered in patients who fail to demonstrate appropriate improvement. Viruses, fungi, parasites, and *Mycobacteria* all have longer time courses for improvement than expected for uncomplicated community acquired bacterial pneumonia. *Obstructing endobronchial lesions* (congenital and acquired) must also be considered. Foreign bodies, pulmonary sequestration, cystic adenomatoid malformations, and postinfectious bronchiectasis are a few conditions that can result in impaired clearance of a pulmonary infiltrate. Finally, a number of *noninfectious causes* can mimic community-acquired pneumonia, both symptomatically and radiographically, but resolve slowly. These include such entities as bronchiolitis obliterans, hypersensitivity pneumonitis, eosinophilic pneumonia, aspiration, and Wegener granulomatosis. Sarcoidosis and pulmonary alveolar proteinosis may also produce a similar picture but are rare in children.

Initially, evaluation of a patient with slowly resolving pneumonia should include an attempt to identify the offending organism. Blood, sputum, pleural, bronchoalveolar lavage, or

lung biopsy can provide tissue for Gram stain and/or culture and thereby guide antibiotic choice. If these do not provide an explanation, serologic testing may be helpful (anti-neutrophil cytoplasmic antibodies [ANCA] for Wegener granulomatosis). Chest CT scans (thin-cut and/or high-resolution), flexible fiberoptic bronchoscopy, and lung biopsy (transbronchial, percutaneous, video-assisted thoracoscopic, or open) may also be helpful.

Chapter 391 - Bronchiectasis

Oren Lakser

Bronchiectasis is a disease characterized by irreversible abnormal dilatation of the bronchial tree and likely represents a common end stage of a number of nonspecific and unrelated antecedent events. Its incidence has been decreasing, especially in developed countries.

Pathophysiology and Pathogenesis.

In the developed world, cystic fibrosis is the most common cause of clinically significant bronchiectasis. Other conditions associated with bronchiectasis include ciliary dyskinesia, immune deficiency syndromes, and infection, especially pertussis, measles, and tuberculosis. Bronchiectasis can also be congenital. *Williams-Campbell syndrome*, in which there is an absence of annular bronchial cartilage, and *Marnier-Kuhn syndrome* (congenital tracheobronchomegaly), in which there is a connective tissue disorder, are two such examples. Other disease entities associated with bronchiectasis include *right middle lobe syndrome* (chronic extrinsic compression of right middle lobe bronchus by hilar lymph nodes) and *yellow nail syndrome* (pleural effusion, lymphedema, discolored nails).

In general, three basic mechanisms are involved in the pathogenesis of bronchiectasis. Obstruction can occur because of tumor, foreign body, impacted mucus caused by poor mucociliary clearance, external compression, bronchial webs, and atresia. Infections due to *Bordetella pertussis,* measles, rubella, togavirus, respiratory syncytial virus, and *Mycobacterium tuberculosis* induce chronic inflammation, progressive bronchial wall damage, and dilatation. Chronic inflammation, similarly, contributes to the mechanism by which obstruction leads to bronchiectasis. The mechanism by which bronchiectasis occurs in congenital forms is likely related to abnormal cartilage formation, as described earlier. The common thread in the pathogenesis of bronchiectasis is difficulty clearing secretions and recurrent infections.

Bronchiectasis can present in any combination of three pathologic forms. In *cylindrical* bronchiectasis the bronchial outlines are regular but there is diffuse dilatation of the bronchial unit. The bronchial lumen ends abruptly because of mucus plugging. In *varicose* bronchiectasis the degree of dilatation is greater and local constrictions cause an irregularity of outline resembling varicose veins. There may also be small sacculations. In *saccular* (cystic) bronchiectasis, bronchial dilatation progresses and results in ballooning of bronchi that end in fluid- or mucus-filled sacs. This is the most severe form of bronchiectasis.

Clinical Manifestations.

The most common complaints in patients with bronchiectasis are cough and copious purulent sputum production. Younger children may swallow the sputum. Hemoptysis is seen with some frequency. Fever can occur with infectious exacerbations. Anorexia and poor weight gain may occur as time passes. Physical examination typically reveals crackles localized to the affected area, but wheezing may also occur. In severe cases, dyspnea and hypoxemia may occur. Pulmonary function studies may demonstrate an obstructive, restrictive, or mixed pattern. Typically impaired diffusion capacity is a late finding.

Diagnosis.

Chest radiographs of patients with bronchiectasis tend to be nonspecific. Typical findings may include increase in size and loss of definition of bronchovascular markings, crowding of bronchi, and loss of lung volume. In more severe forms, cystic spaces, occasionally with air-fluid levels and honeycombing, may occur. Compensatory overinflation of unaffected lung may be seen.

Bronchography was formerly the best technique to demonstrate bronchiectasis. This technique requires sedation and airway administration of a radiographic contrast agent. Today, bronchography may still be used before surgery for lung biopsy or resection to provide better localization.

Thin-section high-resolution CT scanning has replaced bronchography as the gold standard, because it has equal or better sensitivity and specificity and is less invasive. CT provides further information on disease location, presence of mediastinal lesions, and the extent of segmental involvement. The addition of radiolabeled aerosol inhalation to CT scanning can provide further information. The CT findings in patients with bronchiectasis typically include cylindrical (“tram lines,” “signet ring appearance”), varicose (bronchi with “beaded contour”), cystic (cysts in “strings and clusters”), or mixed forms.

Treatment.

The initial therapy for patients with bronchiectasis is medical and aims at decreasing airway obstruction and controlling infection. Chest physiotherapy (postural drainage), antibiotics, and bronchodilators are essential. It is not unusual that 2–4 wk of parenteral antibiotics are necessary to adequately manage acute exacerbations. Antibiotic choice is dictated by the identification and sensitivity of organisms found on deep throat, sputum, or bronchoalveolar fluid cultures. Chronic prophylactic oral antibiotics may be beneficial. Any underlying disorder (e.g., immunodeficiency, aspiration) that may be contributing must also be addressed. When localized bronchiectasis becomes more severe or resistant to medical management, segmental or lobar resection may be warranted. Lung transplantation has also been performed in patients with bronchiectasis.

Prognosis.

Overall, the prognosis for patients with bronchiectasis has improved considerably over the past few decades. Earlier recognition or prevention of predisposing conditions, more powerful and wide-spectrum antibiotics, and improved surgical outcomes are likely reasons.

Chapter 392 - Pulmonary Abscess

Oren Lakser

Pulmonary abscesses are composed of thick-walled purulent material formed as a result of lung infection and lead to destruction of lung parenchyma, cavitation, and central necrosis. Lung abscesses are much less common in children than in adults. A *primary* lung abscess occurs in a previously healthy patient with no underlying medical disorders. A *secondary* lung abscess occurs in a patient with underlying or predisposing conditions.

Pathology and Pathogenesis.

A number of conditions predispose children to the development of pulmonary abscesses, including pneumonia, cystic fibrosis, gastroesophageal reflux, tracheoesophageal fistula, immunodeficiencies, postoperative complications of tonsillectomy and adenoidectomy, seizures, and a variety of neurologic diseases. In children, aspiration of infected materials is the predominant source of the organisms causing abscesses. Initially, a pneumonitis impairs drainage of fluid or the aspirated material. Inflammatory vascular obstruction occurs, leading to tissue necrosis, liquefaction, and abscess formation. Abscess can also occur as a result of pneumonia and hematogenous seeding from another site.

If the aspiration event occurred in the recumbent position, the right and left upper lobes and apical segment of the right lower lobes are the dependent areas most likely to be affected. If the child was upright, the posterior segments of the upper lobes are dependent and therefore most likely to be affected. Primary abscesses are found most often on the right side, whereas secondary lung abscesses, particularly in immunocompromised patients, have a predilection for the left side.

Both anaerobic and aerobic organisms can cause lung abscesses. Common anaerobic bacteria that can cause a pulmonary abscess include *Bacteroides* species, *Fusobacterium* species, and *Peptostreptococcus* species. Abscesses may be caused by aerobic organisms such as *Streptococcus* species, *Staphylococcus aureus, Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*. All patients with a lung abscess should have aerobic and anaerobic cultures as part of their

work-up.

Clinical Manifestations.

The most common symptoms of pulmonary abscess in the pediatric population include cough, fever, tachypnea, dyspnea, chest pain, vomiting, sputum production, weight loss, and hemoptysis. Physical examination typically reveals tachypnea, dyspnea, retractions with accessory muscle use, decreased breath sounds, and dullness to percussion in the affected area. Crackles and occasionally a prolonged expiratory phase may be heard on lung examination.

Diagnosis.

Diagnosis is most commonly made on chest radiography. Classically, the chest radiograph shows a parenchymal inflammation with a cavity containing an air-fluid level. A chest CT scan can provide better anatomic definition, including location and size. The determination of the etiologic bacteria can be very helpful in guiding antibiotic choice. Gram stain of sputum may provide an early clue as to the class of bacteria involved. However, sputum cultures typically yield mixed bacteria and therefore are not always reliable. Attempts to avoid contamination from oral flora include direct lung puncture and percutaneous (aided by CT guidance), bronchoscopic, and transtracheal aspiration, now the primary diagnostic procedure. Bronchoscopic aspiration may be complicated by massive intrabronchial aspiration, and therefore great care should be taken during the procedure.

Treatment.

Conservative management is recommended. Most experts advocate a 2–3 wk course of parenteral antibiotics for uncomplicated cases, followed by a course of oral antibiotics to complete a total of 4–6 wk. Antibiotic choice should be guided by Gram stain and culture but initially should include aerobic and anaerobic coverage. Treatment regimens should include a penicillinase-resistant agent active against *S. aureus* and anaerobic coverage, typically with clindamycin or ticarcillin/clavulinic acid. If gram-negative bacteria are suspected or isolated, an aminoglycoside should be added.

For severely ill patients or those who fail to improve after 7–10 days of appropriate antimicrobial therapy, surgical intervention should be considered. Minimally invasive percutaneous aspiration techniques, often with CT guidance, have been used with increasing frequency. Infrequently, in rare complicated cases, thoracotomy with lobectomy and/or decortication may be necessary.

Prognosis.

Overall, prognosis for children with primary pulmonary abscesses is excellent. The presence of aerobic organisms seems to be a negative prognostic indicator, particularly in those with secondary lung abscesses. Most children become asymptomatic within 7–10 days, although the fever may persist for as long as 3 wk. Radiologic abnormalities usually resolve in 1–3 mo but can persist for years.

Chapter 393 - Cystic Fibrosis

Thomas F. Boat

Cystic fibrosis (CF) is an inherited multisystem disorder of children and adults, characterized chiefly by obstruction and infection of airways and by maldigestion and its consequences. It is the most common life-limiting recessive genetic trait among whites. A dysfunction of epithelialized surfaces is the predominant pathogenetic feature and is responsible for a broad, variable, and sometimes confusing array of presenting manifestations and complications.

CF is the major cause of severe chronic lung disease in children and is responsible for most exocrine pancreatic insufficiency during early life. It is also responsible for many cases of salt depletion, nasal polyposis, pansinusitis, rectal prolapse, pancreatitis, cholelithiasis, and insulin-dependent hyperglycemia. CF may present as failure to thrive and occasionally as cirrhosis or other forms of hepatic dysfunction. Therefore, this disorder enters into the differential diagnosis of many pediatric conditions.

Genetics.

CF occurs in approximately 1/3,500 white live births and 1/17,000 black infants in the United States. The estimated incidence worldwide varies from 1/377 live births in parts of Brittany to 1/90,000 Asian infants in Hawaii. Generally, the CF gene is most prevalent among Northern and Central Europeans and in individuals who come from these areas.

CF is inherited as an autosomal recessive trait. All of the gene mutations that contribute to the CF syndrome occur at a single locus on the long arm of chromosome 7. The CF gene codes for a protein of 1,480 amino acids called the *CF transmembrane regulator* (CFTR). CFTR is expressed largely in epithelial cells of airways, the gastrointestinal tract (including pancreas and biliary

system), the sweat glands, and the genitourinary system. CFTR has ion channel and regulatory functions that are perturbed variably by the different mutations. The most prevalent mutation of CFTR is the deletion of a single phenylalanine residue at amino acid 508 (?F508). This mutation is responsible for the high incidence of CF in northern European populations and is considerably less frequent in other populations, such as those in southern Europe and Israel. Approximately 50% of individuals with CF and Northern European ancestry are homozygous for ?F508. The remainder of patients have an extensive array of mutations, none of which has a prevalence of more than several per cent, except in circumscribed populations. For example, the W1282X mutation occurs in 60% of the Ashkenazi Jews with CF. The relationship between genotype and phenotype is highly complex. Mutations categorized as “severe” (e.g., ?F508) are associated almost uniformly with pancreatic insufficiency. Several mutations (e.g., 3849+10?Kb C>T) are found in patients with normal sweat chloride concentrations. Severity of lung disease and presence of liver disease cannot be predicted by genotype. This suggests a major environmental (acquired) component of organ system dysfunction or perhaps the presence of other genes that modify the CF phenotype. For example, variant alleles of the mannose-binding lectin, a key factor in systemic innate immunity, are associated with more serious lung infections and reduced survival.

Using probes for 30 of the most frequent mutations, the genotype of 80–90% of Americans with CF can be ascertained. Increasing the number of probes to 70 improves mutation ascertainment by only a few per cent. Thus, not all children with CF can be identified by DNA testing as routinely performed. In special cases, sequencing the *CFTR* gene is necessary to establish the genotype. The presence of polymorphisms in both *CFTR* genes does not always cause CF manifestations.

The high frequency of the CF gene has been hypothetically ascribed to resistance to the morbidity and mortality associated with cholera through the ages. Cultured CF intestinal epithelial cells homozygous for the ?F508 mutation are unresponsive to the secretory effects of cholera toxin.

Pathogenesis.

Four long-standing observations are of fundamental pathophysiologic importance: failure to clear mucous secretions, a paucity of water in mucous secretions, an elevated salt content of sweat and other serous secretions, and chronic infection limited to the respiratory tract. The relationships among these findings were unclear until the early 1980s when it was demonstrated that there is a greater negative potential difference across the respiratory epithelia of CF patients than across the respiratory epithelia of control subjects. Aberrant electrical properties were also demonstrated for CF sweat gland duct epithelium. Subsequent studies demonstrated that the membranes of CF epithelial cells are unable to secrete chloride ions in response to cyclic adenosine monophosphate (AMP)–mediated signals, and that, at least in the respiratory tract, excessive amounts of sodium are absorbed through these membranes (Fig. 393–1). These defects can be traced to a dysfunction of CFTR (Fig. 393–2).

After isolation of the *CFTR* gene and its characterization, it became clear that cyclic AMP-stimulated chloride conductance was a function of CFTR itself and that this function was absent in epithelial cells with many different mutations of the *CFTR* gene. CFTR mutations appear to fall into five classes, albeit with some overlap: I, defective CFTR production owing to premature transcription termination signals; II, defective CFTR processing and trafficking to the apical membrane (e.g., ?F508); III,

defective regulation of chloride channel function from mutations in CFTR phosphorylation or adenosine triphosphate–binding sites; IV, defective chloride conductance caused by missense mutations in the membrane-spanning domains of CFTR that line the channel; and V, abnormal splicing of CFTR. The importance of these

Figure 393-1 The net ion flow across normal and cystic fibrosis (CF) airway epithelia under basal conditions (large arrows). Because water follows salt movement, the predicted net flux of water would be from the airway lumen to the submucosa and would be greater across CF epithelia. The increased Na^+ absorption by CF cells is associated with an increased amiloride-sensitive Na^+ conductance across the apical (luminal) membrane and increased Na^+ ,K^+ -ATPase sites at the basolateral membrane. The cAMP-mediated apical membrane conductance of Cl^- associated with the CF transmembrane regulator (CFTR) does not function in CF epithelia, but an alternative, calcium-activated Cl^- conductance is present in normal and CF cells. It is postulated that CF cells have a limited ability to secrete Cl^- and absorb Na^+ in excessive amounts, limiting the water available to hydrate secretions and allow them to be cleared from the airways lumen. (From Knowles MR: Contemporary perspectives on the pathogenesis of cystic fibrosis. New Insights Cystic Fibrosis 1:1, 1993.)

functional categories is not clear, because they do not correlate with specific clinical features or their severity. Rather, clinical features correlate with the residual CFTR activity. Genotypes causing 99% loss of CFTR activity cause lung disease and pancreatic insufficiency; pancreatic function is retained with 95% loss, and 90% loss results in isolated congenital bilateral absence of the vas deferens or idiopathic chronic pancreatitis.

The postulated epithelial pathophysiology in airways involves an inability to secrete salt and secondarily to secrete water in the presence of excessive reabsorption of salt and water. The proposed outcome is insufficient water on the airway surface to form a periciliary liquid layer and hydrate secretions. Desiccated secretions become more viscous and elastic (rubbery) and are harder to clear by mucociliary and other mechanisms. Altered mucus rheology may be aggravated by low HCO_3^- and a more acidic pH. These secretions are retained and obstruct airways, starting with those of the smallest caliber, the bronchioles. Airflow obstruction at the level of small airways is the earliest observable physiologic abnormality of the respiratory system.

It is plausible that similar pathophysiologic events take place in the pancreatic and biliary ducts (and in the vas deferens), leading to desiccation of proteinaceous secretions and obstruction. Because the function of sweat gland duct cells is to absorb rather than secrete chloride, salt is not retrieved from the isotonic primary sweat as it is transported to the skin surface; chloride and sodium levels consequently are elevated.

Chronic infection in CF is limited to the endobronchial spaces of the airways. The most likely explanation for infection is a sequence of events starting with failure to clear inhaled bacteria promptly and then proceeding to persistent colonization and an inflammatory response in airway walls. An alternative hypothesis, that abnormal CFTR creates an inflammatory state before first infection or amplifies the inflammatory response to initial viral infection, is based on lung lavage evidence of the presence

Figure 393-2 The predicted structure of a cystic fibrosis transmembrane regulator (CFTR) shows that the molecule is anchored in the cell membrane by two membrane-spanning domains (MSD1, MSD2). These domains form a channel through which chloride and probably water can pass. Two nucleotide-binding domains (NBD1, NBD2) interact with ATP to provide energy for CFTR functions. The R domain has many sites for phosphorylation by cAMP-dependent kinases. This domain is involved in the regulation of CFTR functions such as chloride conductance. The most common CFTR mutation, ?F508, is localized to the NBD1 region. This region and the NBD2 site are particularly susceptible to mutation. However, mutations associated with typical manifestations of CF occur in all domains. (From Welsh MJ, Anderson MP, Rich DP, et al: Cystic fibrosis transmembrane conductance regulator. *Neuron* 8:821, 1992.)

of cytokines such as interleukin-8 and neutrophils in the absence of recovered bacteria within the first months of life. More recent evidence supports the contention that CF airway inflammation may be more exuberant but still secondary to early viral or transient bacterial infection. These events occur first in small airways, perhaps because clearance of altered secretions is more difficult from these regions. Chronic bronchiolitis and bronchitis are the initial lung manifestations, but after months to years, structural changes in airway walls produce bronchiolectasis and bronchiectasis.

The agents of airway injury include neutrophil products, such as oxidative radicals and proteases, and immune reaction products. With advanced lung disease, infection may extend to peribronchial lung parenchyma. Several inflammatory products, including proteases, are responsible for the mucus hypersecretion that is characteristic of chronic airways disease.

A finding that is not readily explained is the high prevalence of airway colonization with *Staphylococcus aureus, Pseudomonas aeruginosa,* and *Burkholderia cepacia,* organisms that rarely infect the lungs of other individuals. There is evidence that the CF airway epithelial cells or surface liquids provide a favorable environment for harboring these organisms. Furthermore, CF airway epithelium may be compromised in its innate defenses against the organisms, through either acquired or genetic alterations. Antimicrobial activity is diminished in CF secretions. Initially attributed to elevated salt concentrations, the effect is more likely related to hyperacidified surface liquids or other effects on innate immunity. Another puzzle is the propensity for *P. aeruginosa* to undergo mucoid transformation in the CF airways. The complex polysaccharide produced by these organisms generates a biofilm that provides a hypoxic environment and thereby protects *Pseudomonas* against antimicrobial agents.

Although functional deficits may occur in cellular immunity, mucosal immune function, and the alternate pathway for complement as lung infection progresses to an advanced stage, the immune system in CF appears to be fundamentally intact. Nutritional deficits, including fatty acid deficiency, have been implicated as predisposing factors for respiratory tract infection. The 10–15% of individuals who retain substantial exocrine pancreatic function have statistically lower sweat chloride values, delayed onset of colonization with *P. aeruginosa,* and slower deterioration of lung function. However, nutritional factors are only contributory in part because preservation of pancreatic function does not preclude development of typical lung

disease.

Pathology.

Striking changes are characteristically observed in the organs that secrete mucus. Eccrine sweat glands and parotid salivary glands, including ducts, are not involved pathologically despite abnormalities in the electrolyte content of their secretory product.

The earliest pathologic lesion in the *lung* is that of bronchiolitis (i.e., mucus plugging and an inflammatory response in the walls of the small airways). With time, mucus accumulation and inflammation extend to the larger airways (bronchitis). Goblet cell hyperplasia and submucosal gland hypertrophy become prominent pathologic expressions of a hypersecretory state, which is most likely a response to chronic airway infection. Organisms appear to be confined to the endobronchial space; invasive bacterial infection is not characteristic. With long-standing disease, evidence of airway destruction such as bronchiolar obliteration, bronchiolectasis, and bronchiectasis becomes prominent. Scanning electron microscopy of the airway surface appears normal, except for scattered areas of squamous cell metaplasia, although freeze-fracture studies have found alterations of tight junctions and apical membrane changes that are probably caused by chronic inflammation. Bronchiectatic cysts and emphysematous bullae or subpleural blebs are frequent with advanced lung disease, the upper lobes being most commonly involved. These enlarged air spaces may rupture and cause pneumothorax. Interstitial disease is not a prominent (common) feature, although areas of fibrosis appear eventually. True emphysema occurs but is not a general pathologic finding. Bronchial arteries are enlarged and tortuous, contributing to a propensity for hemoptysis in bronchiectatic airways. Small pulmonary arteries eventually display medial hypertrophy, which would be expected in secondary pulmonary hypertension.

The *paranasal sinuses* are uniformly filled with secretions, and the lining contains hyperplastic and hypertrophied secretory elements. Polypoid lesions within the sinuses, mucopyocele, and erosion of bone have been reported. The nasal mucosa may contain inflammatory cells, be edematous, and form large or multiple polyps, usually from a base surrounding the ostia of the maxillary and ethmoidal sinuses.

The *pancreas* is usually small, occasionally cystic, and often difficult to find at postmortem examination. The extent of involvement varies at birth. In infants, the acini and ducts are often distended and filled with eosinophilic material. In 85–90% of patients, the lesion progresses to complete or almost complete disruption of acini and replacement with fibrous tissue and fat. Infrequently, foci of calcification may be seen on radiographs of the abdomen. The islets of Langerhans contain a normal number of ß cells, although they may begin to show architectural disruption by fibrous tissue during the 2nd decade of life.

The *intestinal tract* shows only minimal changes. Esophageal and duodenal glands are often distended with mucous secretions. Concretions may form in the appendiceal lumen or cecum. Crypts of the appendix and rectum may be dilated and filled with secretions.

Focal biliary cirrhosis secondary to blockage of intrahepatic bile ducts is uncommon in early life, although it is responsible for occasional cases of prolonged neonatal jaundice. This lesion becomes more prevalent and extensive with age and is found in 25% or more of patients at postmortem examination.

Infrequently, this process proceeds to symptomatic multilobular biliary cirrhosis that has a distinctive pattern of large irregular parenchymal nodules and interspersed bands of fibrous tissue. In addition, approximately 30% of patients have fatty infiltration of the liver, in some cases despite apparently adequate nutrition. At autopsy, hepatic congestion secondary to cor pulmonale is frequently observed. The gallbladder may be hypoplastic and filled with mucoid material and not infrequently contains stones. The epithelial lining often displays extensive mucous metaplasia. Atresia of the cystic duct and stenosis of the distal common bile duct have been observed.

Mucus-secreting *salivary glands* are usually enlarged and display focal plugging and dilatation of ducts.

Glands of the uterine cervix are distended with mucus, and copious amounts of mucus collect in the cervical canal. Endocervicitis may be prevalent in teenagers and young women. In more than 95% of males, the body and tail of the epididymis, the vas deferens, and the seminal vesicles are obliterated or atretic.

Generalized amyloidosis has been reported rarely (see Chapter 154).

Clinical Manifestations.

Mutational heterogeneity and environmental factors appear responsible for highly variable involvement of the lung, pancreas, and other organs. A list of presenting manifestations is lengthy, although pulmonary and gastrointestinal presentations predominate (Table 393–1).

RESPIRATORY TRACT.

Cough is the most constant symptom of pulmonary involvement. At first, the cough may be dry and hacking, but eventually it becomes loose and productive. In older patients, the cough is most prominent on arising in the morning or after activity. Expectorated mucus is usually purulent. Some patients remain asymptomatic for long periods or seem to have prolonged but intermittent acute respiratory infections. Others acquire a chronic cough within the first weeks of life or they repeatedly have pneumonia. Extensive bronchiolitis is attended by wheezing, which is a frequent symptom during the 1st years of life. As lung disease progresses, exercise intolerance, shortness of breath, and failure to gain weight or grow are noted. Exacerbations of lung symptoms, presumably owing to more active airways infection, eventually require hospitalization for effective treatment. Finally, cor pulmonale, respiratory failure, and death supervene. Colonization with *Burkholderia cepacia* may be associated with particularly rapid pulmonary deterioration and death.

The rate of progression of lung disease is the chief determinant of morbidity and mortality. The course of lung disease, however, is largely independent of genotype. A few mutations (e.g., R117H) may substantially or even fully spare the lungs. Male gender and exocrine pancreatic sufficiency also are associated with a slower rate of pulmonary function decline.

TABLE 393-1 -- **Presenting Features of More Than 20,000 Cystic Fibrosis Patients in the United States**

Feature	%
Acute or persistent respiratory symptoms	50.5
Failure to thrive, malnutrition	42.9
Abnormal stools	35.0
Meconium ileus, intestinal obstruction	18.8
Family history	16.8
Electrolyte, acid-base abnormality	5.4
Rectal prolapse	3.4
Nasal polyps, sinus disease	2.0
Hepatobiliary disease	0.9
Other*	1.0–2.0

Data from the Patient Registry, Cystic Fibrosis Foundation, Bethesda, MD.

**Includes pseudotumor cerebri, azoospermia, acrodermatitis-like rash, vitamin deficiency states, hypoproteinemic edema, hypoprothrombinemia with bleeding, meconium plug syndrome.*

However, early insults to the lungs (e.g., severe viral infections) are likely to be a major determinant of pulmonary outcome.

Early physical findings include increased anteroposterior diameter of the chest, generalized hyperresonance, scattered or localized coarse crackles, and digital clubbing. Expiratory wheezes may be heard, especially in young children. Cyanosis is a late sign. Common pulmonary complications include atelectasis, hemoptysis, pneumothorax, and cor pulmonale and usually appear beyond the 1st decade of life.

Even though radiographically the paranasal sinuses are virtually always opacified, acute sinusitis is infrequent. Nasal obstruction and rhinorrhea are common, caused by inflamed, swollen mucous membranes or, in some cases, nasal polyposis. Nasal polyps are most troublesome between 5–20 yr of age.

INTESTINAL TRACT.

In 15–20% of newborn infants with CF, the ileum is completely obstructed by meconium (meconium ileus). The frequency is greater (~30%) among siblings born subsequent to a child with meconium ileus, reflecting a higher prevalence in certain genotypes. Abdominal distention, emesis, and failure to pass meconium appear within the first 24–48?hr of life (see Chapter 91.1). Abdominal radiographs (Fig. 393–3) show dilated loops of bowel with air-fluid levels and frequently a collection of granular, “ground glass” material in the lower central abdomen. Rarely, meconium peritonitis results from intrauterine rupture of the bowel wall and can be detected radiographically by the presence of peritoneal or scrotal calcifications. Meconium plug syndrome occurs with increased frequency in infants with CF but is less specific than meconium ileus for this condition. Ileal obstruction with fecal material *(distal intestinal obstruction syndrome* or *meconium ileus equivalent)* occurs in older patients, causing cramping abdominal pain and abdominal distention.

More than 85% of affected children show evidence of maldigestion from exocrine pancreatic insufficiency. Symptoms include frequent, bulky, greasy stools and failure to gain weight even when food intake appears to be large. Characteristically, stools contain readily visible droplets of fat. A protuberant abdomen, decreased muscle mass, poor growth, and delayed maturation are typical physical signs. Excessive flatus may be a problem. A number of mutations are associated with preservation of some exocrine pancreatic function, including R117H and 3849+10kbC?T. Individuals homozygous for ?F508 virtually all have pancreatic insufficiency.

Less common gastrointestinal manifestations include intussusception, fecal impaction of the cecum with an asymptomatic right lower quadrant mass, and epigastric pain owing to duodenal inflammation. Acid or bile reflux with esophagitis symptoms is common in older children and adults. Subacute appendicitis and periappendiceal abscess have been encountered. Rectal prolapse is relatively frequent. Occasionally, hypoproteinemia with anasarca appears in malnourished infants, especially if children are fed soy-based preparations. Neurologic dysfunction (dementia, peripheral neuropathy) and hemolytic anemia may occur because of vitamin E deficiency. Deficiency of other fat-soluble vitamins is occasionally symptomatic. For example, hypoprothrombinemia owing to vitamin K deficiency may result in a bleeding diathesis. Clinical manifestations of other fat-soluble vitamin deficiencies, such as decreased bone density and night blindness, have been noted. Rickets is rare.

BILIARY TRACT.

Biliary cirrhosis becomes symptomatic in only 2–3% of patients. Manifestations may include icterus, ascites, hematemesis from esophageal varices, and evidence of hypersplenism. A neonatal hepatitis-like picture and massive hepatomegaly owing to steatosis have been reported. Biliary colic secondary to cholelithiasis may occur in the 2nd decade of life. Liver disease occurs independent of genotype.

PANCREAS.

In addition to exocrine pancreatic insufficiency, evidence for hyperglycemia and

glycosuria including polyuria and weight loss may appear, especially after 10 yr of age when

---

Figure 393-3 *A* and *B*, Contrast enema in a newborn infant with abdominal distention and failure to pass meconium. Notice the small diameter of the sigmoid and ascending colon and dilated, air-filled loops of small intestine. Several air-fluid levels in the small bowel are seen on the upright lateral view.

8% of individuals acquire diabetes. In most cases, ketoacidosis does not occur, but eye, kidney, and other vascular complications have been noted in patients living 10 yr or more after the onset of hyperglycemia. Recurrent, acute pancreatitis occurs occasionally in individuals who have residual exocrine pancreatic function.

GENITOURINARY TRACT.

Sexual development is often delayed, but only by an average of 2 yr. More than 95% of males are azoospermic because of failure of development of wolffian duct structures, but sexual function is generally unimpaired. The incidence of inguinal hernia, hydrocele, and undescended testis is higher than expected. Adolescent females may experience secondary amenorrhea, especially with exacerbations of pulmonary disease. Cervicitis and accumulation of tenacious mucus in the cervical canal have been noted. The female fertility rate is diminished. Pregnancy is generally tolerated well by women with good pulmonary function but may cause a progression of pulmonary disease and even death in those with moderate or advanced lung problems.

SWEAT GLANDS.

Excessive loss of salt in the sweat predisposes young children to salt depletion episodes, especially during the time of gastroenteritis and during warm weather. These children present with hypochloremic alkalosis. Frequently, parents notice salt “frosting” of the skin or a salty taste when they kiss the child. A few genotypes (e.g., 3849+10kbC?T) are associated with normal sweat chloride values.

Diagnosis and Assessment.

The diagnosis of CF has been based for many years on a positive quantitative sweat test (Cl^- = 60?mEq/L) in conjunction with one or more of the following: typical chronic obstructive pulmonary disease, documented exocrine pancreatic insufficiency, or a positive family history. New diagnostic criteria have been recommended to include additional testing procedures (Box 393–1).

Box 393-1. Diagnostic Criteria for Cystic Fibrosis

Presence of typical clinical features (respiratory, gastrointestinal, or genitourinary)

OR

A history of CF in a sibling

OR

A positive newborn screening test

PLUS

Laboratory evidence for CFTR dysfunction:

Two elevated sweat chloride concentrations obtained on separate days

OR

Identification of two CF mutations

OR

An abnormal nasal potential difference measurement

SWEAT TESTING.

The sweat test, using pilocarpine iontophoresis to collect sweat and chemical analysis of its chloride content, remains the standard approach to diagnosis. The procedure requires care and accuracy. A 3-mA electric current is used to carry pilocarpine into the skin of the forearm and locally stimulate the sweat glands. After washing the arm with distilled water, sweat is collected on filter paper or gauze (or with a capillary tube) that has been placed on the stimulated skin and covered to prevent evaporation. After 30–60?min, the filter paper is removed, weighed, and eluted in distilled water. A chloridometer is recommended for the analysis of chloride in these samples. The amount of sweat collected should be measured and reported. For reliable results, at least 50?mg and preferably 100?mg of sweat should be collected. In infants, it may be necessary to use the upper back to obtain enough sweat. Reliable testing may be difficult in the first few weeks of life because of low

sweat rates. Positive results should be confirmed;

a negative result should be repeated if suspicion of the diagnosis remains.

More than 60?mEq/L of chloride in sweat is diagnostic of CF when one or more other criteria are present. Threshold levels of 40?mEq/L for infants have been suggested. Values between 40 and 60?mEq/L suggest CF at all ages and have been reported in cases with typical involvement. In healthy adults, the sweat chloride values increase slightly, but a value of 60?mEq/L still adequately differentiates CF from other conditions. Chloride concentrations in sweat are somewhat lower in individuals who retain exocrine pancreatic function but remain within the diagnostic range. False-negative test results may be encountered in children with hypoproteinemic edema.

Non-CF conditions associated with elevated concentrations of sweat electrolytes include untreated adrenal insufficiency, ectodermal dysplasia, hereditary nephrogenic diabetes insipidus, glucose-6-phosphatase deficiency, hypothyroidism, hypoparathyroidism, familial cholestasis, pancreatitis, mucopolysaccharidoses, fucosidosis, and malnutrition. Most of these conditions can be easily distinguished from CF by clinical criteria.

OTHER DIAGNOSTIC TESTS.

The finding of increased potential differences across nasal epithelium, the loss of this difference with topical amiloride application, and the absence of a voltage response to a ß-adrenergic agonist have been used to confirm the diagnosis in patients with equivocal or frankly normal sweat chloride values. Failure to sweat when a combination of isoproterenol and atropine is injected into the skin has also been used to characterize CF variants.

PANCREATIC FUNCTION.

Exocrine pancreatic dysfunction is clinically apparent in many patients. However, documentation is desirable if there are questions about the functional status of the pancreas. Measurement of fat balance with a 3-day stool collection or direct documentation of enzyme secretion after duodenal intubation and pancreozymin-secretin stimulation are reliable measures but are cumbersome or invasive for children and are not used routinely. Quantitation of trypsin and chymotrypsin activity in a fresh stool sample is a useful screening test but is not definitive. Measurement of immunoreactive trypsinogen in serum reliably distinguishes patients with CF, with and without pancreatic insufficiency, after 7 yr of age but not before that time. Other indirect measures of pancreatic enzyme secretion are available but have limited or unproven clinical value. Endocrine pancreatic dysfunction may be more prevalent than previously recognized. Some have advocated yearly monitoring of glycosylated hemoglobin levels after 10 yr of age. This approach is more sensitive than spot checks of blood and urine glucose levels.

RADIOLOGY.

Pulmonary radiologic findings suggest the diagnosis but are not specific. Hyperinflation of lungs occurs early and may be overlooked in the absence of infiltrates or streaky densities. Bronchial thickening and plugging and ring shadows suggesting bronchiectasis usually appear first in the upper lobes. Nodular densities, patchy atelectasis, and confluent infiltrates follow. Hilar lymph nodes may be prominent. With advanced disease, impressive hyperinflation with markedly depressed diaphragms, anterior bowing of the sternum, and a narrow cardiac shadow are noted. Cyst formation, extensive bronchiectasis, dilated pulmonary artery segments, and segmental or lobar atelectasis are often apparent. Typical progression of lung disease is seen in Figure 393–4 . CT of the chest can be used to detect and localize thickening of bronchial airway walls, mucus plugging, focal hyperinflation, and early bronchiectasis (Fig. 393–5); it generally is not used for routine evaluation of chest disease.

Radiographs of paranasal sinuses reveal panopacification and often failure of frontal sinus development. Fetal ultrasonography may suggest ileal obstruction with meconium early in the 2nd trimester, but this finding is not predictive of meconium ileus at birth.

PULMONARY FUNCTION.

Standard pulmonary function studies are not obtained until 5–6 yr of age, by which time most patients show the typical pattern of obstructive pulmonary involvement (see Chapters 357 and 359). Decrease in the midmaximal flow rate is an early functional change, reflecting small airway obstruction. This lesion also affects the distribution of ventilation and increases the alveolar-arterial oxygen difference. The findings of obstructive airway disease and modest responses to a bronchodilator are consistent with the diagnosis of CF at all ages. Residual volume and functional residual capacity are increased early in the course of lung disease. Restrictive changes, characterized by declining total lung capacity and vital capacity, correlate with extensive lung injury and fibrosis and are a late finding. Testing several times a year can be used to evaluate the course of the pulmonary involvement. Select CF centers are equipped to measure airflow patterns of sedated infants, but this procedure is usually done in the context of research studies. A few patients reach adolescent or adult life with normal pulmonary function and without evidence of overinflation.

MICROBIOLOGIC STUDIES.

The finding of *S. aureus* or *P. aeruginosa* on culture of the lower airways (e.g., sputum) strongly suggests a diagnosis of CF. In particular, mucoid forms of *Pseudomonas* are virtually diagnostic of CF in children. *B. cepacia* recovery also suggests CF. Increasingly, fiberoptic bronchoscopy is used to gather lower respiratory tract secretions of infants and young children who do not expectorate.

HETEROZYGOTE DETECTION AND PRENATAL DIAGNOSIS.

Mutation analysis should be fully informative when testing potential carriers or a fetus provided that mutations within the family have been previously identified. Testing a spouse of a carrier with a standard panel of probes is approximately 90% sensitive. The rationale for prenatal detection of risk and termination of pregnancy is currently a matter of considerable discussion. A 1977 National Institutes of Health Consensus Conference recommendation to offer prenatal testing to all couples planning to have children as well as individuals with a family history of CF and partners of CF women has been reconsidered because of the medicolegal implications. In addition, termination of pregnancy is a less popular option because expected longevity is approximately 3 decades on average, with promise for an even better prognosis in the future.

NEWBORN SCREENING.

Most newborns with CF can be identified by determination of immunoreactive trypsinogen in blood spots, coupled with confirmatory sweat or DNA testing. This screening test is at best only 95% sensitive. Although newborn diagnoses can prevent early nutritional deficiencies and improve long-term growth, there is as yet no compelling evidence that early diagnosis improves pulmonary, and therefore long-term, outcome. A number of states now screen newborns for CF, but the case for routine newborn screening remains debatable. A stronger case for screening will emerge when therapies that reverse the fundamental defect are available.

Treatment.

The treatment plan should be comprehensive and linked to close monitoring and early, aggressive intervention.

GENERAL APPROACH TO CARE.

Initial efforts after diagnosis should be intensive and include baseline assessment, initiation of treatment, clearing of pulmonary involvement, and education of the patient and parents. Follow-up evaluations are scheduled every 2–3 mo because many aspects of the condition require careful monitoring. An interval history and physical examination should be obtained at each visit. A sputum sample or, if that is not available, a lower pharyngeal swab taken during or after a forced cough is obtained for culture and antibiotic susceptibility studies. Even asymptomatic patients may produce sputum after forced exhalations or pharyngeal stimulation with a swab. Because irreversible loss of pulmonary function from low-grade infection can occur gradually and without acute

symptoms, emphasis is placed on a thorough pulmonary history. Box 393–2 lists symptoms and signs that suggest the need for more intensive antibiotic and physical therapy. Immunoprophylaxis specifically against rubeola, pertussis, and influenza is essential. A nurse, respiratory therapist, social worker, dietitian, and psychologist should participate in the care program as needed. Considerable education and empowerment for families and older children to take responsibility for care is likely to result in the best adherence to daily care programs.

Figure 393-4 Roentgenographic progression of cystic fibrosis lung disease from the diagnosis in infancy to 18 yr of age. *A*, Admitted with cough and wheezing at 2 mo of age. Notice the mild increase in bronchovascular markings, especially in the upper lobe areas. *B*, At age 4 yr, cough was minimal. Bronchovascular markings were mildly increased, and there was some improvement in the upper lobes. The wheeze never recurred. *C* and *D*, At age 13 yr, there was minimal cough and occasional sputum production. The bronchovascular markings were generally further increased, with early bronchiectatic changes in the right upper lobe. The lateral view does not suggest overinflation. *E* and *F*. Age 18 yr. During adolescence, cough and sputum production increased even though outpatient antibiotic therapy was intensified. Small-volume hemoptysis, occasional paroxysms of cough, and weight loss as well as increased nodular infiltrates (especially in the right upper lobe) and hyperinflation (as seen on the lateral view) led to the first hospitalization since infancy. Height and weight were maintained in the 25th–50th percentile.

Because secretions of CF patients are not adequately hydrated, attention in early childhood to oral hydration, especially during warm weather or with acute gastroenteritis, may prevent exacerbation of problems with clearance of mucus from airways. For the same reason, intravenous therapy for dehydration should be initiated early.

The goal of therapy is to maintain a stable condition for prolonged periods. This can be accomplished for most patients by interval evaluation and adjustments of the home treatment program. However, some children have episodic acute or low-grade chronic lung infection that progresses. For these patients, 2 wk or more of intensive inhalation and physical therapy and intravenous antibiotics are indicated. Intravenous antibiotics may be required infrequently or as often as every 2–3 mo. Significant

Figure 393-5 CT images of the chest in CF. *A*, A 12-yr-old boy with moderate lung disease. Airway and parenchymal changes are present throughout both lungs. Multiple areas of bronchiectasis *(arrows)* and mucus plugging *(arrowheads)* are seen. *B*, A 19-yr-old girl has mostly normal lung with one area of saccular bronchiectasis in the right upper lobe *(arrows)* and a focal area of peripheral mucus plugging in the right lower lobe *(arrowhead)*. Lung density is heterogeneous with areas of normal lung *(open arrow)* and areas of low attenuation reflecting segmental and subsegmental air trapping *(asterisk)*.

improvement in pulmonary function and the child's well-being is usually achieved.

The basic daily care program varies depending on the age of the child, the degree of pulmonary involvement, other system involvement, and the time available for therapy. The major components of this care are pulmonary and nutritional therapy. Because therapy is medication-intensive, iatrogenic problems arise frequently. Monitoring for these complications is also an important part of management (Table

393–2).

PULMONARY THERAPY.

The object is to clear secretions from airways and to control infection. The effectiveness of the overall approach, including continuity of care, frequent evaluations, aggressive intervention, and an optimistic outlook, is more important than variations in the use of individual measures.

Box 393-2. Symptoms and Signs Associated with Exacerbation of Pulmonary Infection in Patients with Cystic Fibrosis

SYMPTOMS

Increased frequency and duration of cough

Increased sputum production

Change in appearance of sputum

Increased shortness of breath

Decreased exercise tolerance

Decreased appetite

Feeling of increased congestion in the chest

SIGNS

Increased respiratory rate

Use of accessory muscles for breathing

Intercostal retractions

Change in results of auscultatory examination of chest

Use of accessory muscles for breathing

Intercostal retractions

Change in results of auscultatory examination of chest

Decline in measures of pulmonary function consistent with the presence of obstructive airway disease

Fever and leukocytosis

Weight loss

New infiltrate on chest radiograph

From Ramsey B: Management of pulmonary disease in patients with cystic fibrosis. N Engl J Med 335:179, 1996.

When a child is not doing well, every potentially useful aspect of therapy should be considered.

INHALATION THERAPY.

Aerosol therapy is used to deliver medications and water to the lower respiratory tract. Some agents such as bronchodilators can be delivered by metered-dose inhaler with or without a spacer. The mainstay is intermittent delivery using a compressor that drives a hand-held nebulizer. The basic aerosol solution is 0.45–0.9% saline. In patients with reactive airways, albuterol or other ß-agonists are added. Alternatively, or in addition, cromolyn sodium or inhaled corticosteroids can be administered. ß-Agonists may decrease Pa_{O_2} by increasing ventilation-perfusion mismatch, a problem if the Pa_{O_2} is marginal.

When the airway pathogens are resistant to oral antibiotics or when the infection is difficult to control at home, aerosolized antibiotics may reduce symptoms, improve pulmonary function, and alleviate the need for hospitalization. (See Aerosolized Antibiotic Therapy.)

Human recombinant DNase (2.5?mg), given as a single daily aerosol dose, improves pulmonary function, decreases numbers of pulmonary exacerbations, and promotes a sense of well-being in patients who have moderate disease and purulent secretions. Benefit for those with normal FEV_1 values or advanced lung disease has also been documented. Improvement is sustained for 12 mo or more on continuous therapy. Another mucolytic

TABLE 393-2 -- **Complications of Therapy for Cystic Fibrosis**

Complication	Agent
Gastrointestinal bleeding	Ibuprofen

Hyperglycemia	Corticosteroids (systemic)
Growth retardation	Corticosteroids (systemic, inhaled)
Renal dysfunction	
Tubular	Aminoglycosides
Interstitial nephritis	Semisynthetic penicillins
Hearing loss, vestibular dysfunction	Aminoglycosides
Peripheral neuropathy or optic atrophy, or both	Chloramphenicol (prolonged course)
Hypomagnesemia	Aminoglycosides
Hyperuricemia, colonic stricture	Pancreatic extracts (very large doses)
Goiter	Iodine-containing expectorants
Gynecomastia	Spironolactone
Enamel hypoplasia or staining	Tetracyclines (used in first 8 yr of life)
Note: Common hypersensitivity reactions to drugs are not included.	

agent, *N*-acetylcysteine, is toxic to ciliated epithelium, and repeated administration should be avoided.

CHEST PHYSICAL THERAPY.

This treatment usually consists of chest percussion combined with postural drainage and derives its rationale from the idea that cough clears mucus from large airways, but chest vibrations are required to move secretions from small airways where expiratory flow rates are low. Chest physical therapy (PT) may be particularly useful for patients with CF because they accumulate secretions in small airways first, even before the onset of symptoms. Improvement of pulmonary function generally cannot be demonstrated immediately after this therapy. However, cessation of chest PT in older children with mild to moderate airflow limitation results in deterioration of lung function within 3 wk, and prompt improvement of function occurs when therapy is resumed. Chest PT is recommended one to four times a day, depending on the severity of lung dysfunction. Cough or forced expirations are encouraged after each lung segment is “drained.” Hand-held or vest-type mechanical percussors may be useful for adolescents or young adults. Voluntary coughing, repeated forced expiratory maneuvers with and without positive expiratory pressure, patterned breathing, and use of a hand-held flutter device have all been suggested as additional aids to clearance of mucus. Routine aerobic exercise appears to slow the rate of decline of pulmonary function.

ANTIBIOTIC THERAPY.

Antibiotics are the mainstay of therapy designed to control progression of lung infection. The goal is to reduce the intensity of endobronchial infection and to delay progressive lung damage. The usual guidelines for acute chest infections, such as fever, tachypnea, or chest pain, are often absent. Consequently, all aspects of the patient's history and examination, including anorexia, weight loss, and diminished activity, must be used to guide the frequency and duration of therapy. Antibiotic treatment varies from intermittent short courses of one antibiotic to nearly continuous treatment with one or more antibiotics. Dosages are often two to three times the amount recommended for minor infections because patients with CF have proportionately more lean body mass and higher clearance rates for many antibiotics than do other individuals. Also, it is difficult to achieve effective drug levels of many antimicrobials in respiratory tract secretions.

Oral Antibiotic Therapy. Indications include the presence of respiratory tract symptoms and identification of pathogenic organisms in respiratory tract cultures. Whenever possible, the choice of antibiotics should be guided by in vitro sensitivity testing. Common organisms include *S. aureus,* nontypable *Haemophilus influenzae,* and *P. aeruginosa. B. cepacia* is encountered with increasing frequency. The first two can be eradicated from the respiratory tract in CF, but *Pseudomonas* is more difficult to treat and rarely is eradicated outside of infancy. The usual course of therapy is 2 wk or more, and maximal doses are recommended. Useful oral antibiotics are listed in Table 393–3 . Tetracycline should be avoided in children younger than 9 yr of age. The quinolones are the only broadly effective oral antibiotics for *Pseudomonas* infection, but resistance emerges rapidly. Infection with mycoplasmal or chlamydial organisms has been documented, providing a rationale for the use of macrolides on an empirical basis for flare of symptoms. Additionally, macrolides may reduce the virulence properties of *P. aeruginosa* such as biofilm production and contribute anti-inflammatory effects.

Aerosolized Antibiotic Therapy. *P. aeruginosa* and other gram-negative organisms are frequently resistant to all oral antibiotics. Aerosol delivery of antibiotics offers an option for home delivery of additional agents. Inhaled tobramycin has been studied the most extensively. When given at a dose of 300?mg twice daily on alternate months for 6 mo, *Pseudomonas* density in sputum decreases, fewer hospitalizations are required, and pulmonary function improves by 10%. Toxicity is negligible. This therapy can be recommended for increasing symptoms

TABLE 393-3 -- **Antimicrobial Agents for Cystic Fibrosis Lung Infection**

Route	Organisms	Agents	Dosage (mg/kg/24?:hr)	Doses/24?:hr

Oral	*Staphylococcus aureus*	Dicloxacillin	25–50	4
		Cephalexin	50	4
		Clindamycin	20	3–4
		Amoxicillin-clavulanate	40	3
		Haemophilus influenzae	Amoxicillin	50–100

**Quantity of trimethoprim.*
†Quantity of ticarcillin.
‡In mg per dose.

or to improve long-term function in patients with moderate to severe disease. Other antimicrobials such as ticarcillin (0.5?g) and colistin (20–40?mg) have been used two to four times a day. Sensitization or resistance to inhaled antibiotics may occur, but both are surprisingly infrequent.

Intravenous Antibiotic Therapy. For the patient who has progressive or unrelenting symptoms and signs despite intensive home measures, intravenous antibiotic therapy is indicated. This therapy is usually initiated in the hospital but often is completed on an ambulatory basis. Although many patients improve within 7 days, it is usually advisable to extend the period of treatment to at least 14 days. Permanent intravenous access can be provided for long-term therapy in the hospital or at home.

Intravenous antibiotics commonly used are listed in Table 393–3 . In general, treatment of *Pseudomonas* infection requires two-drug therapy. A third agent may be required for optimal coverage of *S. aureus* or other organisms. Simultaneous administration of aerosolized antimicrobial agents can increase endobronchial concentrations. The aminoglycosides have a relatively short half-life in many patients with CF. The initial parenteral dose, noted in Table 393–3 , is generally given every 8?hr. After blood levels have been determined, the total daily dose should be adjusted. Peak levels of 10?mg/L are desirable, and trough levels should be kept at less than 2?mg/L to minimize the risk of ototoxicity and nephrotoxicity. Once- or twice-a-day aminoglycoside dosing may have advantages over every-8-hr dosing. Changes in therapy should be guided by culture results and by lack of improvement. If patients do not improve, heart failure, reactive airways, and infection with viruses, *Aspergillus fumigatus,* mycobacteria, or other unusual organisms should be considered. *B. cepacia* may be particularly refractory to antimicrobial therapy.

BRONCHODILATOR THERAPY.

Reversible airway obstruction occurs in many children with CF, sometimes in conjunction with frank asthma or acute bronchopulmonary aspergillosis. Reversible obstruction is suggested by improvement of 15% or more in flow rates after inhalation of a bronchodilator. Treatment may include use of ß-adrenergic agonists by aerosol. Cromolyn sodium or ipratropium hydrochloride are alternative agents, but their efficacy has not been studied systematically.

ANTI-INFLAMMATORY AGENTS.

Corticosteroids are useful for the treatment of allergic bronchopulmonary aspergillosis and severe reactive airway disease occasionally encountered in children with CF. Prolonged treatment of standard CF lung disease using an alternate-day regimen initially appeared to improve pulmonary function and diminish hospitalization rates. However, a 4-yr double-blind, multicenter study of this regimen for patients with mild to moderate lung disease found only modest efficacy and prohibitive side effects, including growth retardation, cataracts, and abnormalities of glucose tolerance at a dose of 2?mg/kg and growth retardation at 1?mg/kg. Inhaled corticosteroids have theoretical appeal, but there are few data concerning efficacy and safety. Ibuprofen, given chronically (dose adjusted to achieve a peak serum concentration of 50–100?µg/mL) over 4 yr, is associated with an impressive slowing of disease progression, particularly in younger patients with mild lung disease. Side effects of nonsteroidal anti-inflammatory drugs have been encountered (see Table 393–2).

ENDOSCOPY AND LAVAGE.

Treatment of obstructed airways sometimes includes tracheobronchial suctioning or lavage, especially if atelectasis or mucoid impaction is present. Bronchopulmonary

lavage may be performed by the instillation of saline or a mucolytic agent through a fiberoptic bronchoscope. Antibiotics (usually gentamicin or tobramycin) may also be instilled directly at lavage, transiently achieving a much higher endobronchial concentration than can be obtained by using intravenous therapy. There is no evidence for sustained benefit from repeated endoscopic or lavage procedures.

EXPECTORANTS.

Systemic drugs, such as iodides and guaiphenesin, do not effectively assist with the removal of secretions from the respiratory tract.

TREATMENT OF PULMONARY COMPLICATIONS.

A number of pulmonary complications require extra attention or special measures.

Atelectasis. Lobar atelectasis occurs relatively infrequently; it may be asymptomatic and noted only at the time of a routine chest radiograph. Aggressive intravenous therapy with antibiotics

---

and increased chest PT directed at the affected lobe may be effective. If there is no improvement in 5–7 days, bronchoscopic examination of the airways may be indicated. If the atelectasis does not resolve, continued intensive home therapy is indicated, because atelectasis may resolve during a period of weeks or months. Persistent atelectasis may be asymptomatic. Lobectomy should be considered only if expansion is not achieved and the patient has progressive difficulty from fever, anorexia, and unrelenting cough (see Chapter 400).

Hemoptysis. Endobronchial bleeding usually reflects airway wall erosion secondary to infection. With increasing numbers of older patients, hemoptysis has become a relatively frequent complication. Blood streaking of sputum is particularly common. Small volume hemoptysis (<20?mL) should not trigger panic and is usually viewed as a need for intensified antimicrobial and chest PT. When the hemoptysis is persistent or increases in severity, hospital admission is indicated. Massive hemoptysis, defined as total blood loss of 250?mL or more within a 24-hr period, is rare in the first decade and occurs in less than 1% of adolescents, but it requires close monitoring and the capability to replace blood losses rapidly. Chest PT is often discontinued until 12–24?hr after the last brisk bleeding episode and is then reinstituted gradually. Patients should receive vitamin K for an abnormal prothrombin time. During brisk hemoptysis, the child and parents require a great deal of reassurance that the bleeding will stop. Blood transfusion is not indicated unless there is hypotension or the hematocrit is significantly reduced. Ticarcillin or nonsteroidal inflammatory drugs may interfere with platelet function and aggravate hemoptysis. Bronchoscopy rarely reveals the site of bleeding. Lobectomy is to be avoided, if possible, because functioning lung should be preserved. Bronchial artery embolization can be useful to control persistent, significant hemoptysis.

Pneumothorax. Pneumothorax (also see Chapter 403) is encountered in less than 1% of children and teenagers, but it is more frequently encountered in older patients and may be life-threatening. The episode may be asymptomatic but is often attended by chest and shoulder pain, shortness of breath, or hemoptysis. An open thoracotomy through a small incision with plication of blebs, apical pleural stripping, and basal pleural abrasion is recommended after the first occurrence and within 24?hr of the diagnosis. This procedure is well tolerated even in cases of advanced lung disease. Intravenous antibiotics are begun on admission. The thoracotomy tube is removed as soon as possible, usually on the 2nd or 3rd postoperative day. The patient can then be mobilized and full postural drainage therapy resumed. Rarely, bilateral simultaneous pneumothorax is encountered; in this case, control of the air leak must be achieved immediately, at least on one side.

Allergic Aspergillosis. This complication occurs in 5–10% of patients and may present as wheezing, increased cough, shortness of breath, or marked hyperinflation (see Chapter 218 and Chapter 388). In some patients there are new, focal infiltrates on the chest radiograph. The presence of rust-colored sputum, the recovery of *Aspergillus* organisms from the sputum, the demonstration of serum precipitating and specific IgE and IgG antibodies against *A. fumigatus,* or the presence of eosinophils in a fresh sputum sample support the diagnosis. The serum IgE level is usually high. Treatment is directed at controlling the inflammatory reaction with corticosteroids and preventing central bronchiectasis. For refractory cases, oral itraconazole may be required.

Nontuberculous Mycobacteria (NTM) Infection. Injured airways with poor clearance my be colonized by *Mycobacterium avium-complex,* but also *M. abscessus* and *M. kansasii.* Distinguishing endobronchial colonization (frequent) from invasive infection (infrequent) is challenging. Persistent fevers coupled with acid-fast organisms on sputum smear suggest infection. Treatment is prolonged and requires multiple antimicrobial agents. Symptoms may improve, but NTM is usually not cleared from the lungs.

Bone and Joint Complications. Hypertrophic osteoarthropathy causes elevation of the periosteum over the distal portions of long bones and bone pain, overlying edema, and joint effusions. Acetaminophen or ibuprofen may provide relief. Control of lung infection usually reduces symptoms. Intermittent arthropathy unrelated to other rheumatologic disorders occurs occasionally, has no recognized pathogenesis, and usually responds to nonsteroidal anti-inflammatory agents. Rib fractures from vigorous coughing require pain management. These and other fractures may stem from diminished bone mineralization, the result of reduced vitamin D absorption, corticosteroid therapy, and perhaps other factors.

Acute Respiratory Failure. Acute respiratory failure (see Chapter 57.3 and Chapter 357.1) in patients with mild to moderate lung disease rarely occurs and is usually the result of a severe viral or other infectious illness. Because patients with this complication can regain their previous status, intensive therapy is indicated. In addition to aerosol, postural drainage, and intravenous antibiotic treatment, oxygen is required to raise the arterial P_{O_2} to greater than 50?mm Hg (Sa_{O_2} = 85). An increasing P_{CO_2} may require ventilatory assistance. Endotracheal or bronchoscopic suction may be necessary and can be repeated daily. Right-sided heart failure may occur and should be treated vigorously. Recovery is often slow. Intensive intravenous antibiotic therapy and postural drainage should be continued for 1–2 wk after the patient has

regained baseline status.

Chronic Respiratory Failure. Patients acquire chronic respiratory failure after prolonged deterioration of lung function. Although this can occur at any age, it is seen most frequently in adult patients. Because a long-standing Pa_{O_2} less than 50?mm?Hg promotes the development of right-sided heart failure, patients usually benefit from low-flow oxygen to raise arterial P_{O_2} to 55?mm?Hg or greater. Increasing hypercapnia may prevent the use of optimal F_{IO_2} . Most patients improve somewhat with intensive antibiotic and pulmonary therapy measures and can be discharged from the hospital. Low-flow oxygen therapy at home is needed, especially with sleep. Nocturnal noninvasive ventilatory support, if tolerated, can improve ventilation. These patients almost always display cor pulmonale and should be maintained on a reduced salt intake and diuretics. Caution should be exercised to avoid alkalosis that results from diuretic-induced bicarbonate retention. Chronic pain (headache, chest pain, abdominal pain, and limb pain) is frequent at the end of life and responds to judicious use of analgesics, including opioids.

Lung transplantation is an option for end-stage lung disease (see Chapter 435.2). Criteria for referral include an FEV_1 less than 30% predicted. At best, 50% of patients are now surviving 5 yr or more, and lung function as well as quality of life generally improve remarkably. Because of bronchiolitis obliterans and other complications, transplanted lungs cannot be expected to function for the lifetime of a recipient. The demand for donor lungs exceeds the supply and waiting lists as well as duration of waits continue to grow.

Heart Failure. Some patients experience reversible right-sided heart failure (see Chapter 357.1 and Chapter 434) as the result of an acute event such as a viral infection or pneumothorax. Individuals with long-standing, advanced pulmonary disease, especially those with severe hypoxemia (Pa_{O_2} < 50?mm?Hg), often acquire chronic right-sided heart failure. The mechanisms include hypoxemic pulmonary arterial constriction and loss of the pulmonary vascular bed. Pulmonary artery wall changes contribute to increased vascular resistance with time. Evidence for concomitant left ventricular dysfunction is often found. Cyanosis, increased shortness of breath, increased liver size with a tender margin, ankle edema, jugular venous distention, an unusual weight gain, increased heart size seen on chest

radiograph, or evidence for right-sided heart enlargement seen on electrocardiogram or echocardiogram help to confirm the diagnosis. Furosemide (1?mg/kg administered intravenously)- induced diuresis confirms the suspicion of fluid retention. Repeated doses are often required at 24–48?hr intervals to reduce fluid accumulation and accompanying symptoms. Concomitant use of spironolactone may protect against potassium depletion and facilitate long-term diuresis. Hypochloremic alkalosis complicates the chronic use of loop diuretics. Digitalis is not effective in pure right-sided failure, but it may be useful when there is an associated left-sided dysfunction. The arterial P_{O_2} should be maintained at greater than 50?mm?Hg if at all possible. Intensive pulmonary therapy including intravenous antibiotics is most important. Initially, the salt intake should be limited to 2?g sodium/24?hr. Volume overload and antibiotics with high sodium content should be avoided. No clear-cut long-term benefit from pulmonary vasodilators has been demonstrated. In the past, heart failure usually meant death within several months. However, the prognosis has been improving, and a number of patients survive for 5 yr or more after the appearance of heart failure. Lung transplantation is the best option for reversal (see Chapter 435.2).

NUTRITIONAL THERAPY.

Up to 90% of patients have complete loss of exocrine pancreatic function and inadequate digestion of fats and proteins. They require diet adjustment, pancreatic enzyme replacement, and supplementary vitamins.

Diet. Many infants at the time of diagnosis have nutritional deficits. Young infants who present with wheezy breathing and are fed soy protein formulas do not use this protein well and may acquire hypoproteinemia with anasarca. Infants do not routinely need formulas containing predigested protein and medium-chain triglycerides. A low-fat, high-protein, high-calorie diet was generally recommended in the past for older children. Some children on this diet are deficient in essential fatty acids. With the advent of improved pancreatic enzyme products, normal amounts of fat in the diet are usually tolerated and preferred. Not infrequently, parent-child interactions at feeding time are maladaptive, and behavioral interventions can improve caloric intake.

Most individuals have a higher than normal caloric need because of increased work of breathing and perhaps because of increased metabolic activity related to the basic defect. When anorexia of chronic infection supervenes, weight loss occurs. Encouragement to eat high-calorie foods may be useful, but weight gain generally is not realized unless lung infection is controlled. With advanced lung disease, weight stabilization or gain has been achieved by nocturnal feeding via nasogastric tube or percutaneous enterostomy or by intravenous hyperalimentation. Long-term benefits of these interventions for lung function, quality of life, and psychologic well-being are less clearly substantiated.

Pancreatic Enzyme Replacement. Extracts of animal pancreas given with ingested food reduce but do not fully correct stool fat and nitrogen losses. Enzyme dosage and product should be individualized for each patient. Enteric-coated, pH-sensitive enzyme microspheres are most often prescribed. Several strengths up to 20,000?IU of lipase/capsule are available. Administration of large doses has been linked to colonic strictures requiring surgery. Consequently, enzyme replacement should not exceed 2,500 lipase units/kg/meal. One to three capsules/meal is sufficient for most patients; infants need 2000–4000 lipase units per feeding mixed with applesauce. Snacks should be covered. The microsphere preparations usually are sufficiently effective to permit a liberal diet, which may include homogenized milk. Although children with CF display bile salt malabsorption, enzyme preparations containing bile salts are infrequently needed. The dose of enzymes required usually increases with age, but some teenagers and young adults may later have a decrease in their requirement.

Vitamin and Mineral Supplements. Because pancreatic insufficiency results in malabsorption of fat-soluble vitamins (A, D, E, and K), vitamin supplementation is

recommended. Capsules containing amounts adequate to prevent deficiency of all four vitamins for CF patients are now available. They should be taken daily. Replacement doses may be required when low serum levels are documented or the patient is symptomatic. Infants with zinc deficiency and rash have been reported. In addition, attention should be paid to iron status; in one study almost one third of children with CF had a low serum ferritin concentration.

TREATMENT OF INTESTINAL COMPLICATIONS

Meconium Ileus. When meconium ileus (see Chapter 91.1) is suggested, a nasogastric tube is placed for suction and the infant is hydrated. In some cases diatrizoate (Gastrografin) enemas with reflux of contrast material into the ileum have resulted in the passage of a meconium plug and clearing of the obstruction. Use of this hypertonic solution requires careful correction of water losses into the bowel. Children in whom this procedure fails require operative intervention. Children who are successfully treated generally have a prognosis similar to that of other patients. Infants with meconium ileus should be treated as having CF until adequate sweat testing can be carried out.

Distal Intestinal Obstruction Syndrome (Meconium Ileus Equivalent) and Other Causes of Abdominal Symptoms. Despite appropriate pancreatic enzyme replacement, 2–5% of patients accumulate fecal material in the terminal portion of the ileum and in the cecum, which may result in partial or complete obstruction. For intermittent symptoms, pancreatic enzyme replacement should be continued or even increased and laxatives or stool softeners (milk of magnesia, docusate sodium [Colace], mineral oil) given. Increased fluid intake is also recommended. Failure to relieve symptoms signals the need for large-volume bowel lavage with a balanced salt solution containing polyethylene glycol taken by mouth or by nasogastric tube. When there is complete obstruction, a diatrizoate enema, accompanied by large amounts of intravenous fluids, can be therapeutic. Intussusception and volvulus must also be considered in the differential diagnosis. Intussusception, usually ileocolic, occurs at any age and often follows a 1–2 day history of “constipation.” It can often be diagnosed and reduced by a diatrizoate enema. If a nonreducible intussusception or a volvulus is present, laparotomy is required. Repeated episodes of intussusception may be an indication for cecectomy.

Chronic appendicitis with or without periappendiceal abscess may present with recurrent or persistent abdominal pain, raising the question of need for a laparotomy. A lack of acid buffering in the duodenum appears to promote duodenitis and ulcer formation in some children. Bile reflux is seen in older patients (see following section). Other reasons for surgical procedures include carcinoma of the colon or biliary tract and sclerosing colonopathy.

Gastroesophageal Reflux. Because several factors raise intra-abdominal pressure, including cough and obstructed airways, pathologic gastroesophageal reflux is not uncommon and may exacerbate lung disease secondary to reflex wheezing and repeated aspiration. Dietary, positional, and medication therapy should be considered. Cholinergic agonists are contraindicated because they trigger mucus secretion and progressive respiratory difficulty. Reduction of stomach acid secretion can help, with proton pump inhibitors being the most effective agents. Fundoplication is a procedure of last resort.

Rectal Prolapse. This occurs frequently in infants with CF and less commonly in older children. It is usually related to steatorrhea, malnutrition, and repetitive cough. The prolapsed rectum can usually be replaced manually by continuous gentle pressure with the patient in the knee-chest position. Sedation may be helpful. To prevent an immediate recurrence, the buttocks can be taped closed. Adequate pancreatic enzyme replacement,

decreased fat and roughage in the diet, and control of pulmonary infection result in improvement. Occasionally, a patient may continue to have rectal prolapse and require surgery.

Liver Disease. Liver function abnormalities associated with biliary cirrhosis can be improved by treatment with ursodeoxycholic acid. The ability of bile acids to prevent progression of cirrhosis has not been clearly documented. Portal hypertension with esophageal varices, hypersplenism, or ascites occurs in 2% or fewer of children with CF (see Chapter 348). The acute management of bleeding esophageal varices includes nasogastric suction and cold saline lavage. Sclerotherapy is recommended after an initial hemorrhage. In the past, significant bleeding has also been treated successfully with portosystemic shunting. Splenorenal anastomosis has been the most effective. Pronounced hypersplenism may require splenectomy. The management of ascites is discussed in Chapter 351 .

Obstructive jaundice in newborns with CF requires no specific therapy. Hepatomegaly with steatosis requires careful attention to nutrition and may respond to carnitine repletion. Rarely, biliary cirrhosis proceeds to hepatocellular failure, which should be treated as in other patients with hepatic failure (see Chapter 345 and Chapter 348). End-stage liver disease is an indication for liver transplantation in children with CF, especially if pulmonary function is good.

Pancreatitis. Pancreatitis may be precipitated by fatty meals, alcohol ingestion, or tetracycline therapy. Serum amylase and lipase levels may remain elevated for long periods. Treatment is discussed in Chapter 332 .

Hyperglycemia. Onset occurs most frequently after the 1st decade. Eight percent of 13–18 yr olds and approximately 20% of young adults are treated for hyperglycemia. Prevalence is significantly higher in females and in ?F508 homozygotes. Ketoacidosis is rarely encountered. The pathogenesis includes both impaired insulin secretion and insulin resistance. Glucose intolerance without urine glucose losses is usually not treated; glycosylated hemoglobin levels should be followed at least annually. With persistent glycosuria and symptoms, insulin treatment should be instituted. Oral hypoglycemic agents, with or without drugs that reduce insulin resistance, may be effective. Exocrine pancreatic insufficiency and malabsorption make strict dietary control of hyperglycemia difficult. Corticosteroid therapy should be avoided. The development of significant hyperglycemia favors acquisition of *P. aeruginosa* and *B. cepacia* in the airways and adversely affects pulmonary function.

Thus, careful control of blood sugar is an important goal.

OTHER THERAPY

Nasal Polyps. Nasal polyps (see Chapter 363) occur in 15–20% of patients with CF and are most prevalent in the 2nd decade of life. Local corticosteroids and nasal decongestants occasionally provide some relief. When the polyps completely obstruct the nasal airway, rhinorrhea becomes constant, or widening of the nasal bridge is noticed, surgical removal is indicated; polyps may recur promptly or following a symptom-free interval of months to years. Polyps inexplicably stop developing in many adults.

Salt Depletion. Sweat salt losses can be high, especially in warm arid climates. Children should have free access to salt, and precautions against overdressing infants should be observed. Regimented salt supplements are no longer prescribed. Hypochloremic alkalosis should be suspected in any infant who has had symptoms of gastroenteritis, and prompt fluid and electrolyte therapy should be instituted as needed.

Growth and Maturation. Delayed growth should be vigorously addressed by enhancing nutrition and treating lung disease more vigorously. The risk-benefit ratio of growth hormone or anabolic steroids does not support their widespread use for undersized children with CF. Delayed sexual maturation, often associated with short stature, occurs fairly frequently. Although many have severe pulmonary infection or poor nutrition, delayed puberty also occurs in patients with otherwise mild disease and is not well explained. Adolescents with CF should receive specific counseling through their developing years concerning sexual maturation and reproductive potential.

Surgery. Minor surgical procedures, including dental work, should be performed under local anesthesia if possible. Patients with good or excellent pulmonary status can tolerate general anesthesia without any intensive pulmonary measures before the surgery. Those with moderate or severe pulmonary infection usually do better with a 1–2 wk course of intensive antibiotic treatment before surgery. If this is impossible, prompt intravenous antibiotic therapy is indicated once it is recognized that major surgery is required. The total time of anesthesia should be kept to a minimum. After induction, tracheal suctioning is useful and should be repeated at least at the end of the operation. Patients with severe disease require monitoring of their blood gases and may require ventilatory assistance in the immediate postoperative period.

After major surgery, cough should be encouraged and postural drainage treatments should be reinstituted as soon as possible, usually within 24?hr. Adequate analgesia is important if early effective therapy is to be achieved. For those with significant pulmonary involvement, intravenous antibiotics are continued for 7–14 postoperative days. Early ambulation and intermittent deep breathing are important; an incentive spirometer can also be helpful. After open thoracotomy for treatment of pneumothorax or lobectomy, the chest tube is the greatest single obstacle to effective pulmonary therapy and should be removed as soon as possible so that full postural drainage therapy can resume.

NEW THERAPIES.

Several innovative therapies are under investigation. Approaches include pharmacologic stimulation of alternative chloride transport mechanisms or upregulation of mutated *CFTR,* and lung gene therapy. The lung has proved to be particularly resistant to transfer and expression of the *CFTR* gene. Earlier and more effective control of airway infection and inflammation is another experimental therapeutic goal. The use of megestrol acetate for treating malnutrition is also under study.

Prognosis.

CF remains a life-limiting disorder, although survival has improved dramatically during the past 30–40 yr. Infants with severe lung disease occasionally succumb, but most children survive this difficult period and are relatively healthy into adolescence or adulthood. However, the slow progression of lung disease eventually reaches disabling proportions. Life table data now indicate a median cumulative survival of 32 yr. Male survival is somewhat better than female survival for reasons that are not readily apparent. Children in socioeconomically disadvantaged families have, on average, a much poorer prognosis.

For the most part, children with CF have good school attendance records and do not need to be restricted in their activities. A high percentage eventually attend and graduate from college. Most find satisfactory employment, and an increasing number marry. Transitioning care from pediatric to adult care centers by 18–21 years of age is an important objective and requires a thoughtful, supportive approach.

With increasing life span, a new set of psychosocial considerations has emerged, including dependence-independence issues, self-care, peer relationships, sexuality, sterility, substance abuse, educational and vocational planning, financial burdens, and anxiety concerning health and prognosis. Many of these issues are best addressed in an anticipatory fashion, prior to the onset of psychosocial dysfunction. With appropriate medical and psychosocial support, children and adolescents with CF generally cope well. Achievement of an independent and productive adulthood is a realistic goal for many.

Chapter 394 - Primary Ciliary Dyskinesia (Immotile Cilia Syndrome)

Gabriel G. Haddad

The group of respiratory disorders making up primary ciliary dyskinesia (PCD) have in common the malfunction of airway cilia. The ciliary abnormality is a result of various inherited primary structural defects in the cilia that lead to repeated and chronic lung infections. However, the ciliary malfunction in these diseases is not a result of acquired repeated pulmonary infections.

Characteristics of Cilia

LOCATION AND STRUCTURE.

Airway cilia are located on epithelial surfaces in almost a ubiquitous fashion. They are present in the nose, sinuses, ears, and airways. They are also present in places other than the respiratory epithelium, such as in the fallopian tubes and in sperm. The density of cilia varies, with the majority of cells (50–80%) in the large airways having cilia, far fewer cells in the lower airways having cilia, and no cells in air sacs and alveoli having cilia. The frequency of ciliary beating, or *beatquency,* is 1–20?Hz, with the higher beatquency occurring in the larger airways, correlating with the mucus velocity in various parts of the tracheobronchial tree.

Cilia are finger-like structures that extend from the surface of cells into the lumen of airways. They have a diameter of 0.25?µm and a length of 306?µm. Each cell usually has about 200 cilia on its surface. Each cilia has a trunk, a basal body (where the cilia attaches to the cell), and a crown, which is a specialized structure presumed to be important in cilia attachment to mucus. The trunk is made of an outer cell membrane and axonemes or cytoskeletal protein structures. The latter form a circular array of nine microtubules in pairs with an additional central pair. Each peripheral pair can attach to the other via bridges or dynein arms. Spokes are also cytoskeletal proteins that join peripheral and central microtubules.

FUNCTION.

Cilia beat and move by a sliding motion of microtubules. At the outset of the beating cycle, they bend at the base and move backward, perpendicular to the surface. Subsequently, they extend (“slide”) as they are rotating in a forward motion. These bending and rotating movements, which are clockwise, three-dimensional rotations, are made possible by adenosine triphosphate hydrolysis and the dynein arms, which are adenosine triphosphatases. When visualized under microscopy, airway cilia are seen to coordinate their activity regionally, and waves of ciliary movements (many cilia together) occur. How this is coordinated is not well understood.

The main function of cilia is to transport, through its beating movements, mucus toward the mouth. The effectiveness of this function depends on the beatquency, the composition and thickness of the periciliary fluid and mucus layer above it, and the coordination of ciliary movements. In addition, there are a number of neurochemicals that modulate ciliary beating by increasing beatquency, such as ß-adrenergic compounds, acetylcholine, bradykinins, and serotonin. Alternatively, lowering airway humidity significantly lowers the frequency of ciliary beating. In addition, increasing bacterial loads decreases its beatquency.

Pathology.

The structural abnormalities of these disorders can be seen with electron microscopy. Defects in both inner and outer dynein arms, radial spoke microtubular assembly, and central core cytoskeletal proteins have been described. It is estimated that there are more than 200 polypeptides in the ciliary structure, and primary ciliary dyskinesia is most likely based on the absence of one or several ciliary cytoskeletal proteins. All these structural defects result in ciliary malfunction characterized by either abnormal beating or immotility of cilia and defective mucociliary clearance of airway secretions. The most likely pathogenic sequence is airway mucus retention and failure to clear pathogenic organisms, followed by chronic or frequently recurring respiratory tract infections and, ultimately, injury to airway walls.

Genetics.

PCD occurs in about 1/20,000 whites and has been reported in Japanese patients. It is probably the 3rd most common form of inherited chronic airway disease of white children, following cystic fibrosis (CF) and genetic immunodeficiency states. The inheritance pattern of PCD has not been established. An association between ciliary dyskinesia and hydrocephalus and mental retardation in four male siblings in a Jordanian family has been reported that might be caused by a mutation that affects pulmonary toilet and cerebrospinal fluid movement.

DNAH5 is a dynein heavy-chain gene localized on chromosome 5p. The cilia inner arm dynein heavy-chain gene is important in reducing the frequency of beating, although there is no gross morphologic abnormality in the cilia. This same gene is also critical for the movement of sperm from the uterus into the oviduct of the mouse. Furthermore, mutations in *DNAH5* have been found in patients with PCD. Mutations of this gene also have been described in patients exhibiting randomization of organ left-right asymmetry. It is hypothesized that normal rotation of viscera depends on the motion of ciliated intestinal cells early in development. The absence of ciliary motility allows random rotation; a dynein defect causes left-right asymmetry in the inversus viscerum (iv/iv) mouse model.

Clinical Manifestations.

About 50% of patients with PCD have Kartagener syndrome: situs inversus, chronic sinusitis and otitis,

and airway disease leading to bronchiectasis. However, only about 25% of patients with situs inversus also have PCD. Situs inversus does not establish or exclude the presence of PCD.

The course is variable. Individuals with PCD may have respiratory distress during the newborn period or may survive to adulthood without overt chronic sinusitis and airway disease symptoms. However, in one study of PCD, 100% of children had productive cough, sinusitis, and otitis. A feature that is helpful in differentiating PCD from CF is repeated bouts of acute otitis media or chronic serous otitis. Children diagnosed after several years of life often have been treated with tympanostomy tubes; conductive hearing loss is common. Nasal polyps or clubbing is present in about 20% of patients. Many children with PCD experience frequent wheezing and may have an initial diagnosis of asthma. The hallmark symptom is a chronic, often loose or productive, cough. Pneumonia may supervene, and lower respiratory tract disease can progress to weight loss, diminished exercise tolerance, and bronchiectasis. Respiratory failure in childhood is uncommon, as are lung complications such as pneumothorax and hemoptysis. Lobar atelectasis occurs frequently. Males are frequently infertile and display absent or poor sperm motility.

Diagnosis.

PCD should be suspected in children with chronic or recurring upper and lower respiratory tract symptoms, especially in the presence of substantial middle ear disease. Radiographic or CT imaging shows involvement of the paranasal sinuses. Chest radiographs may demonstrate overinflation, bronchial wall thickening, and peribronchial infiltrates. Often, atelectasis and consolidation are present. Bronchiectasis is best detected by CT scanning (see Chapter 391). The presence of a right-sided heart in a child with chronic respiratory tract symptoms is virtually diagnostic, but this configuration occurs in only 50% of these patients. Pulmonary function testing of older children yields a typical obstructive pattern.

Mucociliary clearance can be assessed in cooperative children by ascertaining the time to taste perception of a saccharin particle placed on the inferior nasal turbinate. Scrapings or brushings of nasal mucosa can be examined directly by light or, preferably, by phase-contrast microscopy for evidence of motility. In most PCD tissue specimens, little or no ciliary motion is seen. However, because substantial motility has been documented in scrapings of several individuals with absent dynein arms, light microscopic examination of living tissue can be used as a screening tool only. The gold standard is quantitative documentation of abnormal structural elements, such as missing dynein arms or random orientation of cilia in nasal or bronchial biopsies or scrapings on electron microscopic examination. Concordance of ultrastructural abnormalities in cilia and sperm is not complete. To avoid acquired ciliary changes, mucosal specimens should not be obtained until 2 wk after an acute respiratory tract infection. Ultrastructural evaluation should be reserved for highly suspicious cases. However, some structural abnormalities are also observed after injury to ciliated epithelial cells by viral infection or sulfur dioxide exposure. Therefore, definitive evidence that any structural alteration represents a discrete form of PCD awaits the identification of specific gene mutations.

Treatment.

Therapy is symptomatic. Cough should be encouraged. Chest physiotherapy assists the clearance of mucus. Antibiotics should be prescribed for evidence of infection of sinuses or lower airways. The choice of antibiotics is best dictated by identification and sensitivity testing of pathogenic organisms, often pneumococcus or untypable *Haemophilus influenzae.* Oral antibiotic administration is usually effective. Bronchodilators can be used for symptomatic wheezing or documentation of reversible airway obstruction. Children should be examined several times each year and followed by periodic chest radiographs and serial pulmonary function testing. Sinus and middle ear symptoms refractory to medical therapy deserve consultation with an otolaryngologist. Surgical intervention may be helpful in selected cases. Prevention of lung infection by measles, pertussis, influenza, and possibly pneumococcal vaccines is highly desirable. Additional preventive measures include avoidance of cigarette smoke and other airway irritants.

Prognosis.

Progression of lung disease appears to be much slower for patients with PCD than for those with CF. With proper treatment, disabling lung disease often can be avoided for long periods. A normal life span is possible.

Chapter 395 - Interstitial Lung Diseases

Michelle S. Howenstine

The interstitial lung diseases (ILD) in infants and children include a group of uncommon, heterogeneous diseases that cause disruption of alveolar gas exchange and symptoms of restrictive lung disease. Knowledge regarding pediatric ILD is limited because of its rare occurrence, varied spectrum of disease, and lack of controlled clinical trials investigating the disease process and treatment measures. The pathophysiology is believed to be more complex than adult disease because the injury occurs during the process of lung growth and differentiation. In ILD, the initial injury causes damage to the alveolar epithelium and capillary endothelium. An exaggerated immune response then recruits oxidants and proteases, resulting in further damage to the lung interstitium and parenchymal units.

Classification and Pathology.

The classification of ILD in children is not standardized, but it is helpful to separate diseases into those of known and unknown etiology (Box 395–1). Respiratory infections caused by adenovirus, influenza, *Chlamydia,* and *Mycoplasma pneumoniae* are usually self-limited illnesses but have been associated with prolonged and progressive lung damage, often in the form of bronchiolitis obliterans. Aspiration is a frequent cause of chronic lung disease in childhood. Children with developmental delay or neuromuscular weakness are at an increased risk for aspiration of food, saliva, or foreign matter secondary to swallowing dysfunction and/or gastroesophageal reflux. An undiagnosed tracheoesophageal fistula can also result in pulmonary complications related to aspiration of gastric contents and interstitial pneumonia. Children experiencing an exaggerated immunologic response to organic dust, molds, or bird antigens may develop hypersensitivity pneumonitis. Children with malignancies also may develop ILD related to the primary malignancy, an opportunistic infection, or secondary to chemotherapy or radiation treatment. In addition, unique forms of ILD

INTERSTITIAL LUNG DISEASES OF KNOWN ETIOLOGY

- Aspiration syndromes
- Chronic infection (viral, bacterial, fungal, parasitic)
    - Immunocompetent host
    - Immunocompromised host
- Bronchopulmonary dysplasia
- Hypersensitivity pneumonitis (and other environmental exposures)
- Lipid storage diseases

INTERSTITIAL LUNG DISEASES OF UNKNOWN ETIOLOGY

- Primary pulmonary disorders
    - Usual interstitial pneumonitis (UIP)
    - Desquamative pneumonitis (DIP)
    - Lymphocytic interstitial pneumonitis (LIP) and related disorders
    - Nonspecific interstitial pneumonitis
    - Pulmonary hemosiderosis
    - Pulmonary infiltrates with eosinophilia
    - Bronchiolitis obliterans
    - Bronchiolitis obliterans with organizing pneumonia (BOOP)

    - Bronchiolitis obliterans
    - Bronchiolitis obliterans with organizing pneumonia (BOOP)

    - Alveolar proteinosis
    - Pulmonary vascular disorders (proliferative and congenital)
    - Pulmonary lymphatic disorders
    - Pulmonary microlithiasis

OTHER DISORDERS WITH PULMONARY INVOLVEMENT

- Connective tissue disorders
- Malignancies
- Histiocytosis
- Sarcoidosis
- Neurocutaneous syndromes

From Fan LL: Pediatric Interstitial Lung Disease. In Schwartz MI, King TE (editors): Interstitial Lung Disease, 3rd ed. Toronto, BC Decker, 1998, p 103.

have been described in infants presenting with chronic tachypnea, retractions, crackles, and hypoxemia (Box 395–2). The prognosis in these diseases is variable.

USUAL INTERSTITIAL PNEUMONITIS (UIP).

This disorder is the most common form of ILD in affected adults but is rare in children. The pulmonary lesion is characterized by a mixed distribution of ongoing inflammation and progressive end-stage fibrosis that is patchy and heterogenous. The diagnosis is made by biopsy; there is no definitive clinical or radiologic feature.

DESQUAMATIVE INTERSTITIAL PNEUMONITIS (DIP).

This disease, also dependent on biopsy diagnosis, demonstrates a uniform, homogeneous process characterized by hyperplasia of alveolar epithelial cells with an accumulation of large macrophages within the air spaces. Fibrosis is usually not seen. A familial form has been described in infants that is unusually severe and often fatal.

LYMPHOCYTIC INTERSTITIAL PNEUMONITIS (LIP).

This most common form of ILD in children is a form of pulmonary lymphoproliferative disease. LIP usually develops in association with conditions of impaired immunity, such as an autoimmune disease or immunodeficiency (e.g., HIV infection). The pulmonary interstitium is invaded by a diffuse infiltrate of mature lymphocytes. Fibrosis is rare. Infection with a virus such as Ebstein-Barr virus is often a contributing factor in the development of pediatric LIP.

ACUTE INTERSTITIAL PNEUMONITIS.

This entity, also known as rapidly progressive interstitial pneumonitis or Hamman-Rich syndrome, is a distinct, rapidly progressive form of ILD. On biopsy, the alveolar damage progresses from an acute exudative process to severe fibrosis. An antecedent injury is often not identified; the fatality rate is greater than 50%.

Clinical Manifestations.

A detailed history is needed to assess the severity of symptoms and the possibility of an underlying systemic disease. Identification of precipitating factors such as exposure to molds or birds or a severe lower respiratory infection is important in establishing the diagnosis and instituting avoidance measures. A positive family history especially in an affected infant is suggestive of a genetic or familial disease, such as a surfactant protein B deficiency (see Chapter 396 and Chapter 397). Tachypnea, cough, dyspnea, and exercise intolerance are present in over two thirds of patients. Symptoms are usually insidious and occur in a continuous, not episodic pattern. Tachypnea and basilar crackles are present in over one half of the patients. Retractions, failure to thrive, clubbing, and wheezing are common complaints. Cyanosis and a prominent second heart sound are suggestive of severe disease. Anemia or hemoptysis suggests a pulmonary vascular disease or pulmonary hemosiderosis. Rashes or joint complaints are consistent with an underlying connective tissue disease.

Box 395-2. Unique Forms of Interstitial Lung Disease in Infancy

- Persistent tachypnea of infancy (PTI)
- Follicular bronchitis/bronchiolitis
- Infantile pulmonary hemosiderosis
- Chronic pneumonitis of infancy
- Surfactant protein B deficiency
- Familial desquamative interstitial pneumonitis (DIP)
- Idiopathic pulmonary fibrosis of infancy

From Fan LL: Pediatric Interstitial Lung Disease. In Schwarz MI, King TE (editors): Interstitial Lung Disease, 3rd ed. Toronto, BC Decker, 1998, p 104.

Diagnosis.

A systematic approach is necessary to establish a definite diagnosis of ILD. Initially, noninvasive tests are used to determine the extent and severity of the disease. Chest radiographic abnormalities may be classified as interstitial, reticular, nodular, reticulonodular, or honeycombed. The chest film also may be normal despite significant clinical impairment and may correlate poorly with the extent of disease. High-resolution CT of the chest better defines the extent and distribution of disease and can provide specific information for selection of a biopsy site. Faster modalities such as helical, spiral, or ultra-fast CT may provide precise resolution of disease patterns in tachypneic infants.

Pulmonary function tests are important in defining the degree of restrictive lung disease and in following the response to treatment. Parallel decreases in functional residual capacity (FRC) and forced expiratory volume in 1 second (FEV_1) are noted. Total lung capacity is usually low. Diffusion of carbon monoxide (DL_{CO}) is usually normal when corrected for the decreased alveolar volume. An impaired DL_{CO} may suggest vascular disease. Bronchoalveolar lavage may provide helpful information regarding secondary infection, bleeding, or aspiration but will not determine the exact diagnosis. Transthoracic lung biopsy for histopathology is necessary for a conclusive diagnosis. Conventional thoracotomy or video-assisted thoracoscopy is used to obtain tissue from children with suspected ILD. Evaluation for possible systemic disease may also be necessary.

Treatment.

Supportive care is essential and includes supplemental oxygen for hypoxia and adequate nutrition for growth failure. Antimicrobial treatment may be necessary for intercurrent infections. Some patients may be responsive to bronchodilators. Anti-inflammatory treatment with corticosteroids remains the initial treatment of choice. Controlled trials in children are lacking, and the clinical responses reported in case studies are variable. The usual dose of prednisone is 1–2?mg/kg/24?hr for 6–8 wk with tapering dictated by clinical response. Alternative, but not adequately evaluated, therapy includes hydroxychloroquine, azathioprine, cyclophosphamide, cyclosporine, methotrexate, intravenous gamma globulin, and pulsed high-dose steroids. Hydroxychloroquine treatment has been successful in some children with classic ILD, particularly those with histopathologic changes of DIP. Lung

transplantation for progressive or end-stage

ILD also has been successful in some infants and children. Appropriate treatment for underlying systemic disease is indicated. Preventative measures include avoidance of all inhalation irritants such as tobacco smoke and, when appropriate, molds and bird antigens. Supervised pulmonary rehabilitation programs may be helpful.

Prognosis.

The overall mortality of ILD is as high as 20% in infants and children. Prognosis is variable and poor in children with pulmonary hypertension, failure to thrive, and severe fibrosis.

Chapter 396 - Pulmonary Alveolar Proteinosis

Aaron Hamvas
Lawrence M. Nogee
F. Sessions Cole

Pulmonary alveolar proteinosis (PAP) is a disorder characterized by the intra-alveolar accumulation of pulmonary surfactant. On histopathologic examination, distal air spaces are filled with a granular, eosinophilic material that stains positively with periodic acid–Schiff reagent and is diastase resistant. Two clinically distinct forms of PAP have been described in children: a fulminant, usually fatal form presenting shortly after birth (termed congenital PAP) and a gradually progressive type presenting in older infants and children and similar to that observed in adults.

Etiology and Pathophysiology.

Although the mechanisms that lead to alveolar proteinosis are undefined, histologic findings suggest that they result in a disruption of pulmonary surfactant metabolism. The early onset of the neonatal form of PAP along with a positive family history of similarly affected newborn infants strongly suggests a genetic basis. For example, an inherited deficiency in surfactant protein-B (SP-B) has been described with some cases of neonatal alveolar proteinosis (see Chapter 397). In addition, several genetically engineered mice with abnormal expression of granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-4 (IL-4), and surfactant protein-D (SP-D) exhibit expanded surfactant pools and alveolar proteinosis owing to increased secretion and/or decreased clearance of otherwise normal pulmonary surfactant from the air space.

Molecular mechanisms in addition to SP-B deficiency have also been described in humans. A deficiency in expression of the ß-subunit of the GM-CSF receptor occurred in four infants with alveolar proteinosis. However, human examples that mimic genetically altered mice have not been identified. Alveolar proteinosis has also been reported in children with lysinuric protein intolerance, a rare autosomal recessive disorder caused by mutations in the cationic amino acid transport peptide SLC7A7. These children develop vomiting, hyperammonemia, and failure to thrive. The relationship between the transport defect and the PAP is unclear.

Alveolar proteinosis also may occur in association with infection, particularly in immunocompromised individuals. However, because the same pathologic process

occurs in severely immunodeficient mice raised in a pathogen-free environment, it is not clear whether this is the result of a secondary infection or the underlying immunodeficiency. Possible autoimmune mechanisms of later-onset alveolar proteinosis have been described in adults with idiopathic primary alveolar proteinosis in whom IgG1 and IgG2 autoantibody directed against GM-CSF can be detected in serum and bronchoalveolar lavage (BAL) fluid. Whether these antibodies are causative or a secondary response in this disorder is unknown. These antibodies have not been identified in infants with alveolar proteinosis.

Clinical Manifestations.

The congenital form of the disorder is immediately apparent in the newborn period and rapidly leads to respiratory failure. There is no gender difference in frequency. Congenital PAP is clinically and radiographically indistinguishable from more common disorders of the newborn that lead to respiratory failure, including pneumonia, generalized bacterial infection, respiratory distress syndrome, and total anomalous pulmonary venous return with obstruction. The differential diagnosis also includes primary persistent pulmonary hypertension, meconium aspiration, and alveolar capillary dysplasia, although the radiologic findings of these disorders usually differ. The incidence of congenital PAP is unknown but thought to be low; it was listed on death certificates of 37 infants who died in the first year of life in a cohort of 1,052,554 births in Missouri between 1979 and 1992.

Alveolar proteinosis in older infants and children is also rare. Males are affected three times as often as females. There may be no identifiable etiologic factor (a primary form), or it may occur in association with malignancy or several inciting agents, including dust, chemicals, and infection, particularly in the setting of systemic immunosuppression (a secondary form). Older infants and children with PAP present with dyspnea, fatigue, cough, weight loss, chest pain, or hemoptysis. In the later stages, cyanosis and digital clubbing may be seen. Pulmonary function testing reveals a restrictive pattern, and arterial blood gases show marked hypoxemia with a chronic respiratory acidosis.

Diagnosis.

Histopathologic examination of lung biopsy specimens is the gold standard for diagnosis in children. The examination of sputum or BAL fluid for surfactant components has been used diagnostically in adults, but these methods have not been validated in children. In patients with alveolar proteinosis caused by mechanisms other than SP-B deficiency, immunohistochemical staining reveals abundant quantities of alveolar and intracellular surfactant proteins A and B. Examination of peripheral blood and/or bone marrow for clonogenic stimulation of monocyte-macrophage precursors, GM-CSF receptor and ligand expression, GM-CSF binding, and anti-GM-CSF autoantibodies are available through research protocols.

Treatment.

Untreated alveolar proteinosis in newborns is rapidly fatal, and no successful medical therapy has been developed. Lung transplantation is the only therapeutic option, but its use is limited by concerns about disease recurrence in the absence of a defined primary mechanism of lung injury.

Repeated bronchoalveolar lavage is a temporizing measure and in some cases is therapeutic for patients with the later-onset form of PAP. In addition, recent trials have suggested that subcutaneous administration of recombinant GM-CSF may improve pulmonary function in some adults with later-onset primary alveolar proteinosis. Although experience is limited, both these interventions have been unsuccessful for the long-term management of newborn infants.

Chapter 397 - Inherited Disorders of Surfactant Protein Metabolism

Aaron Hamvas
Lawrence M. Nogee
F. Sessions Cole

The pulmonary surfactant is a mixture of phospholipids and proteins synthesized, packaged, and secreted by type II pneumocytes that line the distal airways. This mixture forms a monolayer at the air-liquid interface that lowers surface tension at end-expiration of the respiratory cycle and thereby prevents atelectasis and ventilation-perfusion mismatch. Four surfactant-associated proteins have been described: surfactant proteins A and D (SP-A, SP-D) participate in host defense in the lung, whereas surfactant proteins B and C (SP-B, SP-C) contribute to the surface tension–lowering activity of the pulmonary surfactant. Two genes for SP-A and one gene for SP-D are located on human chromosome 10, whereas single genes located on human chromosomes 2 and 8, respectively, encode SP-B and SP-C. Although inherited deficiencies of SP-A or SP-D have not been identified in humans, genetically engineered mice deficient in these proteins are susceptible to viral and bacterial infections and lineages deficient in SP-D accumulate lipids and foamy macrophages in their lungs and develop emphysema and pulmonary fibrosis as they age. Inherited disorders of SP-B and SP-C have been identified in humans and are discussed in detail.

DEFICIENCY OF SURFACTANT PROTEIN B

Genetics.

Over 20 loss-of-function mutations in the SP-B gene have been identified. The most common is a net 2 base-pair insertion in codon 121 (termed 121ins2) that generates a frameshift and interruption of SP-B protein translation. The insertion generates a restriction fragment polymorphism (RFLP) that is useful for diagnosis. This mutation accounts for 60–70% of the alleles found to date in patients identified with SP-B deficiency. Most other mutations have been family specific.

Pathology.

Although SP-B deficiency was first described in a patient with newborn-onset alveolar proteinosis, the histology is neither specific for SP-B deficiency nor universally present in lungs of affected infants. Several SP-B–deficient patients homozygous for the 121ins2 mutation have had histologic features more typical of desquamative interstitial pneumonitis with little detectable alveolar proteinosis at the time of lung transplantation. Other findings are nonspecific and include variable degrees of interstitial fibrosis and alveolar cell hyperplasia. Ultrastructural findings include a lack of tubular myelin, disorganized lamellar bodies, and an accumulation of abnormal-appearing multivesicular bodies, suggesting abnormal lipid packaging and secretion.

Clinical Manifestations.

Infants with an inherited deficiency of SP-B present in the immediate neonatal period with respiratory failure. This autosomal recessive disorder is clinically and radiographically similar to the respiratory distress syndrome of premature infants (see Chapter 90.3) but typically affects full-term infants and is refractory to mechanical ventilation, surfactant replacement therapy, glucocorticoid administration, and extracorporeal membrane oxygenation. SP-B deficiency has been recognized in diverse racial and ethnic groups. Almost all patients have died without lung transplantation, but prolonged survival is possible in cases with a partial deficiency of SP-B. Patients heterozygous for loss-of-function mutations in the SP-B gene are clinically normal as adults and have normal pulmonary function.

Diagnosis.

A rapid, definitive diagnosis can be established with analyses of DNA for known mutations in the SP-B gene, particularly the 121ins2 mutation (using RFLP analysis of polymerase chain reaction–amplified genomic DNA). The sensitivity of genetic diagnosis is limited, however, because assays are not readily available for all known mutations and disease may result from yet unidentified mutations. In families in which a mutation has been previously identified, antenatal diagnosis can be established by molecular assays of DNA from chorionic villus biopsy or amniocytes, which permits advanced planning of a therapeutic regimen. Other laboratory tests remain investigational and include analysis of tracheal effluent by enzyme-linked immunosorbent assay or Western blotting for the presence or absence of SP-B protein and for aberrantly processed precursor proSP-C peptides that have been found in SP-B–deficient human infants and animals. Definitive diagnosis can also be established by immunostaining of lung biopsy tissue for the surfactant proteins. The absence of SP-B protein and abundant expression of the aberrantly processed proSP-C peptide definitively establish a diagnosis of SP-B deficiency. Such studies require a lung biopsy in a critically ill child or may be performed on lung blocks acquired at the time of autopsy. Immunohistochemical assays for SP-B and SP-C are available on a research basis.

Treatment.

Because virtually all patients with SP-B deficiency die within the first year of life, prompt recognition is critical. Conventional neonatal intensive care interventions can maintain extrapulmonary organ function for a limited time (weeks to months). Replacement therapy with commercially available surfactants is ineffective. Lung transplantation has been successful, but the pre-transplant, transplant, and

post-transplant medical and surgical care is highly specialized and only available at pediatric pulmonary transplant centers. The oldest living SP-B–deficient survivors after lung transplantation were born in 1994. The relative scarcity of available infants' lungs for transplantation suggests that gene therapy may be the treatment of choice in the future. Genetic counseling is also important to convey the risks for future pregnancies and the availability of antenatal diagnosis and therapeutic options. Palliative care consultation is also helpful.

SURFACTANT PROTEIN C GENE ABNORMALITIES

Surfactant protein C (SP-C) is a very low molecular weight, extremely hydrophobic protein that, along with SP-B, enhances the surface tension–lowering properties of surfactant phospholipids. It is derived from proteolytic processing of a larger precursor protein (proSP-C). A mutation in the surfactant protein C gene has been identified in a family in which affected individuals did not have respiratory symptoms at birth but developed interstitial lung disease in infancy. The mutation was present on only one allele, consistent with an autosomal dominant inheritance

pattern, and resulted in the production of an abnormal proSP-C protein, decreased amounts of normal proSP-C, and nearly absent mature SP-C. Thus it is unclear if the lung disease resulted from the lack of mature SP-C or from the presence of the abnormal proSP-C protein (which suggests a possible toxic effect from this abnormal peptide).

A preliminary report suggests that SP-C mutations may be associated with other forms of both familial and sporadic chronic lung diseases. However, the epidemiology and the extent of phenotypic and pathologic variability associated with such mutations are unknown. The association of the production of an abnormal protein within the secretory pathway of the alveolar type II cell with lung disease suggests a potential novel mechanism for the initiation of lung injury.

Chapter 398 - Pulmonary Hemosiderosis

Dorr G. Dearborn

Bleeding in the lower respiratory tract in children is unusual but can be life threatening. During infancy and prepubertal childhood, infections, trauma, and foreign bodies are the most common causes of pulmonary hemorrhage. More extensive hemorrhage in this age range can arise from any of the remaining causes listed in Box 398–1 , although the rare immune-related vascular diseases are usually limited to older children and adolescents. After a hemorrhage, macrophages convert the iron of hemoglobin into hemosiderin, hence the term hemosiderosis. Because it takes the macrophage 36–48?hr to form hemosiderin and large numbers of hemosiderin-laden macrophages are probably only resident in the alveoli for about 5 wk, alveolar hemosiderosis is an indicator of previous bleeding and its persistence an indication of continued bleeding. The term pulmonary hemosiderosis should be reserved for persistent or recurrent bleeding.

Pathophysiology and Clinical Manifestations.

Pulmonary hemorrhage can be either focal or diffuse. Focal hemorrhage is usually an acute process in the conducting airways whereas diffuse hemorrhage results from abnormalities of alveolar capillaries with a continuing, sometimes exacerbating course. Notably, alveolar hemorrhage can occur without sufficient blood reaching the central airways to produce hemoptysis (see Chapter 399.2) and may not produce visible infiltrates on chest radiographs. Acute pulmonary hemorrhage that does produce alveolar infiltrates can show rapid clearing in 1–2 days, distinguishing them from infectious infiltrates. An acute hemorrhage is usually accompanied by a drop in hematocrit, an increase in

reticulocyte count, and a stool positive for occult blood. The accompanying respiratory distress, including cough, wheeze, and tachypnea, may be mild and transient or may be sufficiently severe to constitute respiratory failure, depending on the quantity of blood in the alveoli and airways. A more insidious onset may occur with only fatigue, mild dyspnea, and anemia. Diagnosis is most readily confirmed with the use of Prussian blue staining for hemosiderin within alveolar macrophages, obtained most simply by bronchoalveolar lavage (BAL) or by examination of sputum

or gastric aspirates. Even overt pulmonary hemorrhage requiring ventilator support should be followed by alveolar macrophage cytology several (>5) wk after the acute hemorrhage to evaluate continued elevated hemosiderosis (>20% positive cells) denoting a chronic process. Significant alveolar hemorrhage can be ongoing and clinically undetectable except by iron stain cytology of BAL samples.

Secondary Pulmonary Hemosiderosis.

Heart disease that causes a chronic increase in pulmonary venous pressure, such as mitral stenosis, can lead to intrapulmonary hemorrhage and secondary hemosiderosis. Pulmonary arteriovenous malformations can be a component of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) but are seldom accompanied by hemoptysis and hemosiderosis in infancy and childhood. Although pulmonary embolism is not often considered in infants and children, it is a well-known complication of central venous catheters (see Chapter 399). Rarely, pulmonary hemorrhage is seen with hemolytic-uremic syndrome, anaphylactoid purpura, or thrombocytopenic purpura. It can also result from graft versus host disease and is especially a concern at the end of the early neutropenic phase after bone marrow transplant, when endogenous bacterial endotoxin from the intestine can be an inflammatory stimulant in the lung.

Vascular Diseases.

The entire spectrum of the pulmonary vasculature including capillaries can be involved in vascular inflammatory disorders and, in some cases, the inflammatory lesions of the capillaries may be the only pulmonary vascular manifestation of a systemic disorder. Capillary inflammation (capillaritis) may arise from immune processes, including disorders where immune complex deposition or formation can be demonstrated (e.g., systemic lupus erythematosus and Goodpasture syndrome). The role of an immune mechanism is less clear in the necrotizing vasculitis of Wegener granulomatosis. Nephritis or other systemic manifestations are usually evident, but the initial presentation of Goodpasture syndrome (pulmonary hemosiderosis with glomerulonephritis) can be similar to idiopathic pulmonary hemosiderosis with only hemoptysis and iron-deficiency anemia. Adolescents who present with hemoptysis

---

should be evaluated for vascular diseases, including testing for circulating anti–glomerular basement membrane antibodies and antibodies to cytoplasmic components to neutrophils (ANCA). Histopathologic confirmation by biopsy of kidney, lung, or other tissue may be necessary for definitive diagnosis.

The severity of pulmonary involvement is highly variable but can be devastating. Corticosteroid immunosuppression may need to be intensified with azathioprine or cyclophosphamide. Plasmapheresis has been used successfully during acute massive pulmonary hemorrhage in Goodpasture syndrome and microscopic angiitis.

Primary Pulmonary Hemosiderosis with Hypersensitivity to Cow's Milk (Heiner Syndrome).

These patients have the typical picture of idiopathic hemosiderosis often accompanied by chronic rhinitis, recurrent otitis media, gastrointestinal symptoms, and growth retardation. The symptoms improve when cow's milk is removed from the diet and return with its re-introduction. Some patients fail to improve at all on a milk-free diet, and others without multiple milk precipitins have improved. Hypertrophied nasopharyngeal lymphoid tissue can be sufficiently obstructive to lead to secondary cor pulmonale. In general, patients with hemosiderosis and precipitins to cow's milk have a better prognosis than do those with other forms of hemosiderosis, and they may eventually lose their sensitivity to milk. Corticosteroids may be useful, at least during acute bleeding episodes.

Although the pathophysiology is not understood, some infants and children with pulmonary hemosiderosis have circulating IgG antibodies toward cow's milk proteins. Heiner originally detected these “milk precipitins” by immunodiffusion. Antibody levels against cow's milk proteins in excess of 200?g/mL may be observed.

Idiopathic Pulmonary Hemosiderosis (IPH).

This rare disorder of unknown etiology has a reported yearly incidence of between 0.24 (Sweden) and 1.23 (Japan) cases per million children. Onset usually occurs in early in childhood, rarely later than early adult life. Most of the clinical manifestations are related to blood in the alveoli and to the effects of chronic blood loss.

CLINICAL MANIFESTATIONS.

Symptoms are those of recurrent or chronic pulmonary disease and include cough, hemoptysis, dyspnea, wheezing, and occasional cyanosis associated with fatigue and pallor. The cough may be productive of bloody sputum, or the infant or child may simply vomit large quantities of swallowed blood. During acute attacks, which usually last 2–4 days, the child may be febrile. Digital clubbing can be present. The usual clinical features of fever, tachycardia, tachypnea, leukocytosis (including eosinophilia), respiratory distress, and abnormal radiographic findings may suggest bacterial pneumonia, but accompanying anemia and rapid clearing of the chest radiographs should suggest the correct diagnosis. In some children, the early manifestations of illness are related to chronic iron-deficiency anemia and the characteristic pulmonary symptoms do not appear until much later. Although the child may have severe pulmonary manifestations without radiographic abnormalities, seldom is the radiographic picture abnormal before pulmonary symptoms have occurred.

LABORATORY FINDINGS.

The anemia is typically microcytic and hypochromic; serum iron concentration is low, and there may be elevations in bilirubin, urobilinogen, and reticulocyte count. The stool usually contains occult blood, presumably swallowed. Hemosiderin is found in alveolar macrophages obtained by BAL or biopsy and in smears of sputum or gastric aspirates. Radiographic changes range from minimal infiltrates resembling

pneumonia to massive pulmonary involvement with secondary atelectasis. Hilar lymphadenopathy can occur with long-standing disease.

DIAGNOSIS.

This is by the exclusion of known causes for pulmonary hemorrhage and the persistence of elevated or recurrent hemosiderosis beyond the acute 5–8 wk period after a documented pulmonary hemorrhage. Significant continued hemosiderosis is indicated by iron stain cytology on BAL samples showing more than 20% of the macrophages containing hemosiderin or an iron index greater than 50 (scoring 100 macrophages for amount of hemosiderin 0 to 3+ with a maximal score of 300). Culturing of BAL samples for bacteria, viruses, and fungi helps exclude various infectious processes producing hemosiderosis. Although not required for diagnosis, open lung biopsy demonstrates intra-alveolar hemorrhage, large numbers of hemosiderin-laden macrophages, alveolar epithelial hyperplasia, and eventually interstitial fibrosis and small artery hypertensive changes. Absence of immunoglobulin or complement deposition on the alveolar basement membrane virtually excludes immune complex–based vascular disease, and all biopsy specimens should be subjected to this test.

TREATMENT.

A milk-free diet may be helpful in severe cases even if antibodies toward cow's milk proteins are at low titers. Corticosteroids (prednisone, 2–30?mg/kg/24?hr) produce remission in some patients and are of no benefit to others. Maintenance corticosteroid therapy has been used between attacks with variable results, and prolonged survival has been attributed to this therapy in uncontrolled series. More extensive immune suppression with the addition of azathioprine or cyclophosphamide may be helpful. Approximately one half of the patients die within 1–5 yr, usually from acute pulmonary hemorrhage and progressive respiratory failure.

Idiopathic Pulmonary Hemorrhage and Hemosiderosis in Infants.

Acute, idiopathic pulmonary hemorrhage in young infants has been reported in clusters in Cleveland, Chicago, Milwaukee, and Detroit, and sporadic cases have occurred elsewhere in the United States. A case-control study found an association with chronic water damage in the children's homes along with growth of fungi, including *Stachybotrys chartarum*. Although the strength of this association has been questioned, exposure to toxigenic fungi has continued to be found in 90% of the cases. Aerosolized spores from this fungus are sufficiently small to be inhaled out to the distal airways and contain several classes of toxins including trichothecenes, very potent protein synthesis inhibitors, and proteinases with wide substrate specificity. Local release of these toxins and proteinases especially during rapid endothelial basement membrane formation in young infants could lead to fragile capillaries, which would be at risk for stress hemorrhage. Environmental tobacco smoke might also be a contributing factor. In Cleveland, the incidence reached 1.5 cases per thousand live births and mortality was over 30%.

Most of the infants present with acute respiratory distress and overt pulmonary hemorrhage, many requiring ventilator support and blood transfusions. Some infants presenting without frank hemoptysis but with unexplained respiratory failure were found to have pulmonary hemorrhage on tracheal intubation. The subtle presentation and prodromal symptoms of some infants suggests an acute life-threatening event (ALTE). In nasal breathing young infants, hemoptysis may present as an atraumatic epistaxis. Many of the infants have had persistent hemosiderosis continuing for 3–12 mo during which time the infants appear to be at risk for a massive stress-related hemorrhage. Other manifestations observed in some infants include neurologic problems (e.g., seizures and developmental delay), concomitant infection, and hemolysis with hemoglobinuria. Fever and leukocytosis are not usually present.

Treatment for these infants beyond the initial supportive measures has included removing them from their original fungal and smoke environment. In the Cleveland infants, this has led to a 15-fold decrease in the rebleeding frequency. In addition, high-dose corticosteroids (methylprednisolone, 1?mg/kg, intravenously q6h) have been used at the time of the acute hemorrhage followed by oral prednisone (1–2?mg/kg/24?hr) for a few

weeks. Daily or every-other-day prednisone (0.5–1?mg/kg) is maintained until the iron-stained BAL cytology has returned close (iron index < 50/300) to normal (<25/300). Although the use of corticosteroids is empirical, they may be suppressing inflammation, a major component in animal studies of pulmonary stachybotryomycotoxicosis. Anecdotally, several of the deaths of infants in Cleveland occurred in infants who either did not receive corticosteroids or in whom they were discontinued early. Reticulocyte counts and frequent stool guaiac testing help guide the corticosteroid therapy and scheduling of repeat bronchoscopies. **REFERENCES**

Chapter 399 - Pulmonary Hemorrhage, Embolism, and Infarction

Daniel Sloniewsky
Thomas P. Green

399.1 Pulmonary Embolism and Infarction

Epidemiology.

Pulmonary embolism (PE) rarely occurs in children and infants. A prospective epidemiologic study in Canada revealed an incidence of deep venous thrombosis (DVT)/PE of 5.3/10,000 in hospitalized children or 0.07/10,000 in the general pediatric population. Another retrospective autopsy study found an incidence of pediatric PE of 3.7%. Males and females are equally affected, and the highest incidences occur in children younger than 1 yr old and those 11–18 yr old. Most of the patients with PE have serious underlying disorders or precipitating factors. These include the presence of a central venous catheter, immobility, heart disease, the use of oral contraceptives, ventriculoatrial shunts, trauma, infection, dehydration, collagen vascular disease, shock, and obesity.

Children with neoplasms, particularly hematologic malignancies such as acute myeloid leukemia, also are predisposed to PE. The incidence of PE in leukemic patients who receive chemotherapy is 2.9%. The reasons for this predisposition in patients with malignancies are numerous and include the presence of central venous catheters, coagulopathy associated with the disease, and endothelial damage secondary to chemotherapy.

Hematologic disorders are also common in children with PE. Patients with sickle cell anemia may present with intrapulmonary embolism and subsequent infarction, although this is difficult to differentiate from pneumonia. Coagulation abnormalities are common in children with PE (up to 70% in one study) with the presence of antiphospholipid antibodies (particularly lupus anticoagulant) and acquired or inherited deficiencies in proteins C and S being the most common. Other coagulation disorders such as antithrombin III deficiency, dysfibrinogenemia, and the factor V Leiden mutation can also be seen.

Surgery is an important risk factor for emboli, and studies in adults have shown a

predisposition to embolic phenomena up to a month after surgery. In children, scoliosis surgery, in particular, may predispose patients to PE.

Clinical Manifestations and Diagnosis.

When suspecting a pulmonary embolism in a pediatric patient, a thorough medical and family history should be taken. Patients with a family history of coagulation defects or who have had family members die of thrombotic events when younger than 50 yr of age are at high risk. The clinical presentations of PE are varied, and no group of physical findings yields a high positive predictive value. Pleuritic chest pain, dyspnea, apprehension, and cough are the most common complaints, and tachypnea is the most common physical finding. Other potential findings include rales, increased intensity of the pulmonary component of the second heart sound, tachycardia, fever, diaphoresis, phlebitis, wheezing, and hemoptysis. Patients with severe PE can even present with hemodynamic instability, cor pulmonale, and shock.

Laboratory Findings.

These may be as nonspecific as the clinical findings. Arterial blood gas tensions may reveal respiratory alkalosis or arterial hypoxemia or even be normal. An alveolar-arterial gradient, when coupled to a low Pa_{CO_2} , is present in 98% of adult patients with PE. Other laboratory tests that may aid in the diagnosis include D-dimers (which has a specificity of 56%), a complete blood cell count (which may show an elevated white blood cell count), and a coagulation profile. If acquired or familial coagulation disorders are suspected, tests such as fibrinogen, protein C activity, free protein S antigen, antithrombin III activity, DNA analysis for the factor V Leiden mutation, tests for a lupus anticoagulant, and anticardiolipin antibody assays should be considered.

Chest radiographs are often normal in patients with PE and are more useful for excluding other conditions that may mimic PE and in helping interpret ventilation-perfusion scans. Echocardiography and electrocardiography are useful in gathering supporting data for a PE and helping rule out other diseases but have little diagnostic value. An electrocardiogram can show nonspecific ST segment changes and signs of cor pulmonale when present. Echocardiograms are useful to look at cardiac function and ventricular size.

Ventilation-perfusion imaging displays regional blood flow and ventilation defects by noninvasive means and is safe and inexpensive. However, a normal ventilation-perfusion scan does not absolutely exclude a PE and reports are interpreted as high probability, intermediate probability, low probability, very low probability, and normal. Also, the presence of any other conditions that can cause ventilation-perfusion mismatching in the lung (e.g., pneumonia, obstructive lung disease) can limit the utility of this study. In the absence of any concurrent lung disease, and with high clinical suspicion of a PE, the positive predictive value of a high probability scan is 90%.

Helical spiral CT scanning is particularly useful in patients with lung disease. However, this is dependent on the experience of the radiologist and is less useful in patients with emboli to subsegmental pulmonary vessels. Pulmonary angiography is the gold standard diagnostic test for pulmonary embolism and, although invasive and expensive, is relatively safe in patients without pulmonary hypertension or cor pulmonale.

The possibility of deep venous thrombosis should be evaluated in all patients with PE. The femoral and iliac veins and the inferior vena cava are the most common sites of DVT, although emboli can originate from any vessel. Electrical impedance plethysmography and Doppler ultrasonography are useful noninvasive tests for DVT. Venography is the gold standard in the evaluation of thrombosis and should be used in patients with

high clinical suspicion of DVT but negative ultrasound or plethysmography.

Pathophysiology.

The mechanisms behind many of the signs and symptoms of PE arise from ventilation and perfusion mismatches. As perfusion to affected alveolar units decreases secondary to the emboli, there is an increase in alveolar dead space and the ability to eliminate CO_2 is impaired (although hypocarbia may exist secondary to tachypnea). These ventilation-perfusion mismatches can cause hypoxemia and an increased alveolar-arterial oxygen tension gradient. These abnormalities of gas exchange as well as stimulation of lung proprioceptors are responsible for the symptoms of PE.

Increases in pulmonary vascular resistance may also occur with PE, and, as the pressure increases, right ventricular function may become impaired, leading to cor pulmonale. However, it is believed that increases in pulmonary artery pressure are not likely to be evident until the vascular bed is 60% occluded; clinically significant pulmonary hypertension and shock occur with 70–80% occlusion.

Increases in airway resistance may occur when neurohumoral mediators such as serotonin and histamine are released after platelets interact with the clots. The subsequent bronchoconstriction of the small peripheral airways can be reversed with the use of heparin.

Because of the rich vascular supply of the lung and potential for retrograde flow of oxygenated blood from pulmonary veins, pulmonary infarction is an uncommon sequelae of PE. However, it can occur when a pulmonary artery is obstructed and blood subsequently extravasates into an alveolus, whose ability to clear the blood is impaired. Consequently, patients with advanced heart disease and left ventricular failure have a higher incidence of infarction associated with PE.

Treatment.

In treating patients with PE, the basic tenets of resuscitation must be applied first (see Chapter 51.1). Patients with acute respiratory failure may need endotracheal intubation and mechanical ventilation to improve gas exchange. Hemodynamic

instability may require the use of fluid and inotropes, but excessive fluid may cause decompensation of an already impaired right ventricle. Some agents such as dopamine also may exacerbate pulmonary hypertension.

There are three potential approaches to therapy in patients with PE, once they have been stabilized: anticoagulation, thrombolysis, and surgical thrombectomy.

Unfractionated heparin (UFH) should be used in the initial phase of anticoagulation. Heparin, derived from bovine or porcine tissue, acts by accelerating the inhibitory action of antithrombin III on factor Xa and by inactivating thrombin. Continuous intravenous heparin should be administered at 10–25?U/kg/hr after a loading dose of 50–75?U/kg is given. The goal of anticoagulation is an activated partial thromboplastin time of one and one-half to two times the control. Low molecular weight heparin (LMWH) is an alternative to UFH that is equally effective, has a longer half-life and, so, requires only once- or twice-a-day injections, and has better understood pharmacokinetics. It is only excreted by the kidney (UFH binds to numerous plasma proteins). Warfarin (Coumadin), which suppresses vitamin K–dependent clotting factors, should be started 24–48?hr after heparin therapy is begun, because it requires 5 days to reach its full effect. Coagulation profiles need to be followed when using UFH or warfarin, whereas factor Xa levels may be followed with LMWH (although commonly no laboratory tests are followed with LMWH).

Thrombolytic agents such as urokinase, streptokinase, and recombinant tissue plasminogen activator may be useful adjuncts to heparin therapy, particularly in patients with PE and hemodynamic instability. Their utility may be hindered by the presence of antibodies to these agents, and they are contraindicated in patients with active bleeding, recent (<2 mo) cerebrovascular accident, or trauma.

Surgical embolectomy should be reserved for patients with persistent hemodynamic compromise from a PE, despite appropriate medical therapy. This procedure requires an open thoracotomy and has a high mortality. Inferior vena cava (IVC) interruption by catheter-placed filters is indicated in patients with recurrent PE despite medical therapy or in those patients who have a contraindication to anticoagulation. Although these filters are not used commonly in children, they are relatively safe and effective.

Prognosis.

In pediatric patients this depends on the degree of obstruction. Ten per cent of adult patients with acute PE die within 1?hr of the event. Of those who survive, 8% will die even with early diagnosis and therapy and 30% will die if diagnosis is delayed.

399.2 Hemoptysis

Hemoptysis is the expectoration of blood or blood-tinged sputum. It is a rare presenting symptom in pediatric patients and the etiology of the bleeding can be difficult to find. Bleeding can occur from disruption of the pulmonary or bronchial vessels, although bronchial arterial bleeding tends to be more brisk secondary to the higher pressure.

Clinical Manifestations.

First it must be determined if a child is truly experiencing hemoptysis, because blood from the nose or gastrointestinal tract may appear similar to bleeding from the pulmonary system. The blood in hemoptysis is generally bright red and frothy, has an alkaline pH, may contain sputum, and may be accompanied by a cough. Hematemesis is characterized by dark red blood, an acidic pH, the presence of food particles, and nausea.

The differential diagnoses for hemoptysis are listed in Box 399–1 . The most common causes for bleeding are infection, tracheostomy-related problems, the presence of a foreign body, cystic fibrosis, and congenital heart disease. In order to determine the cause of bleeding, a thorough history and physical examination should be performed. For example, a history of chronic lung disease, congenital heart disease, or foreign body aspiration can lead to a faster appropriate diagnostic test. Examination of the oral cavity and nasopharynx must be performed to determine if these are the sources for bleeding.

Laboratory Findings and Diagnosis.

The laboratory evaluation should include a complete blood count to determine the amount of bleeding and a coagulation profile, as well as specific tests for the presumed diagnosis. A chest film may be helpful in determining the presence of a pulmonary or cardiac process or the presence of a foreign body. Computed tomography may be used to help further delineate observations in the chest film, but it should not be used as a screening tool.

Box 399.2-1. Causes of Hemoptysis in Children

- Infection
  - Tracheobronchitis
- Pneumonia
  - Bacterial
  - Tuberculous
  - Fungal (e.g., aspergillosis)
  - Parasitic (e.g., echinococcosis)
- Tracheostomy-related
- Bronchiectasis
  - Cystic fibrosis
  - Ciliary dyskinesia
  - Immunodeficiency
- Foreign body
- Congenital heart disease (mainly with pulmonary vascular obstructive diseases)
- Pulmonary arteriovenous malformations
- Trauma
- Alveolar hemorrhage syndromes
  - Connective tissue disease/vasculitis (e.g., Goodpasture syndrome, Wegener granuloma)
  - Primary pulmonary hemosiderosis (e.g., idiopathic, Heiner syndrome)

disease/vasculitis (e.g., Goodpasture syndrome, Wegener granuloma)

Primary pulmonary hemosiderosis (e.g., idiopathic, Heiner syndrome)

- Pulmonary thromboembolism
- Tumor
  - Bronchial adenoma
  - Metastatic

Modified from Pianosi P, Al-Sadoon H: Hemoptysis in children. Pediatr Rev 1996;17:344–48.

Bronchoscopy may be used as a diagnostic tool and for management. If a patient has persistent bleeding that is not copious, flexible bronchoscopy may be helpful; however, a rigid bronchoscope is necessary to remove foreign bodies and blood clots and to ventilate a patient if necessary.

Treatment.

The management of hemoptysis requires a stable airway, maintenance of gas exchange, and stable hemodynamics. Bleeding more than 8?mL/kg/24?hr is considered life threatening and requires replacement of blood products. Rigid bronchoscopy may be used to apply topical vasoconstrictors such as epinephrine, oxymetazoline, or iced 0.9% saline to curtail bleeding, and balloon catheters may be used to tamponade blood vessels. If this is unsuccessful, selective bronchial artery embolization may be used if the bleeding vessel is identified. Surgical management, including segmentectomy or lobectomy, is considered if embolization fails.

Chapter 400 - Atelectasis

Ranna A. Rozenfeld

Atelectasis, the incomplete expansion or complete collapse of air-bearing tissue, is common in infants and children. Atelectasis results from obstruction of air intake into the alveolar sacs. Segmental, lobar, or whole lung collapse is associated with the absorption of air contained in the alveoli, which are no longer ventilated.

Pathophysiology.

In general, the causes of atelectasis may be divided into five groups (Table 400–1). Viral infections, specifically respiratory syncytial virus (RSV) infection in young children, can cause multiple areas of atelectasis. Massive collapse of one or both lungs is most often a postoperative complication but occasionally results from other causes, such as trauma, asthma, pneumonia, tension pneumothorax, aspiration of foreign material, paralysis, or following extubation. Massive atelectasis is usually produced by a combination of factors, including immobilization or decreased use of the diaphragm and the respiratory muscles, obstruction of the bronchial tree, and abolition of the cough reflex.

Clinical Manifestations.

Symptoms vary with the cause and extent of the atelectasis. A small area is likely to be asymptomatic. When a large area of previously normal lung becomes atelectatic, especially when it does so suddenly, dyspnea accompanied by rapid shallow respirations, tachycardia, cough and often cyanosis occurs. If the obstruction is removed, the symptoms disappear rapidly. Although atelectasis can cause fever, two recent studies have shown no association between atelectasis and fever. Physical findings include limitation of chest excursion, decreased breath sound intensity, and coarse crackles. Breath sounds are decreased or absent over extensive atelectatic areas.

Massive pulmonary atelectasis usually presents with dyspnea, cyanosis, and tachycardia. An affected child is extremely anxious and, if old enough, complains of chest pain. The chest appears flat on the affected side, where decreased respiratory excursion, dullness to percussion, and feeble or absent breath sounds are also noted. Postoperatively atelectasis usually presents within 24?hr after operation but

may not occur for several days.

Acute lobar collapse is a frequent occurrence in patients receiving intensive care. If undetected, it can lead to impaired gas exchange, secondary infection, and subsequent pulmonary fibrosis. Initially hypoxemia may result from ventilation perfusion mismatch. In contrast to adult patients in which the lower lobes and in particular the left lower lobe is most often involved, 90% of cases in children involve the upper lobes and 63%

TABLE 400-1 -- **Anatomic Causes of Atelectasis**

Cause	Clinical Examples
External compression on the pulmonary parenchyma	Pleural effusion, pneumothorax, intrathoracic tumors, diaphragmatic hernia
Endobronchial obstruction completely obstructing the ingress of air	Enlarged lymph node, tumor, cardiac enlargement, foreign body, mucoid plug, broncholithiasis
Intraluminal obstruction of a bronchus	Foreign body, granulomatous tissue, tumor, secretions, including mucus plugs, bronchiectasis, pulmonary abscess, asthma, chronic bronchitis, acute laryngotracheobronchitis
Intrabronchiolar obstruction	Bronchiolitis, interstitial pneumonitis, asthma
Respiratory compromise or paralysis	Neuromuscular abnormalities, osseous deformities, overly restrictive casts and surgical dressings, defective movement of the diaphragm, or restriction of respiratory effort

involve the right upper lobe. There is also a high incidence of upper lobe atelectasis and especially right upper lobe collapse in neonatal intensive care units.

Diagnosis.

The diagnosis of atelectasis can usually be established by chest radiographic examination. Typical findings include volume loss and displacement of fissures. Atypical presentations include atelectasis presenting as a mass-like opacity and atelectasis in an unusual location. Lobar atelectasis may be associated with pneumothorax.

A study of asthmatic children compared chest radiographs with thorax high-resolution computerized tomography (HRCT) and found a chest radiograph abnormality rate of 44% compared with the thorax HRCT scan abnormality rate of 75%, with 38% demonstrating atelectasis on HRCT. The children with atelectasis had increased incidence of right middle lobe syndrome, acute asthma exacerbations, pneumonia, and upper airway infections.

In foreign body aspiration, atelectasis is one of the most common radiographic findings (25–42%). The site of atelectasis usually indicates the site of the foreign body. Atelectasis is more common when patients have a delay in diagnosis of greater than 2 wk duration.

Bronchoscopic examination reveals a collapsed main bronchus when the obstruction is at the tracheobronchial junction and may also disclose the nature of the obstruction.

Massive pulmonary atelectasis is generally diagnosed by chest radiograph. Typical findings include elevation of the diaphragm, narrowing of the intercostal spaces, and displacement of the mediastinal structures and heart toward the affected side (Fig. 400–1).

Treatment.

Treatment depends on the cause of the collapse. If effusion or pneumothorax is responsible, the external compression must first be removed. Often vigorous efforts at cough, deep breathing, and percussion will facilitate expansion. Aspiration with sterile tracheal catheters may facilitate removal of mucus plugs. In many patients, however, early fiberoptic bronchoscopy is indicated for diagnosis and aspiration of obstructing material.

Figure 400-1 *A*, Massive atelectasis of the right lung. The patient has asthma. The heart and the other mediastinal structures are shifted to the right during the atelectatic phase. *B*, Comparison study after re-aeration following bronchoscopic removal of a mucus plug from the right main stem bronchus.

Bronchoscopic examination is immediately indicated if atelectasis is the result of a foreign body or any other bronchial obstruction that may be relieved. For bilateral atelectasis, bronchoscopic aspiration should also be performed immediately. It is also indicated when an isolated area of atelectasis persists for several weeks. If no anatomic basis for atelectasis is found and no material can be obtained by suctioning, the introduction of a small amount of saline followed by suctioning allows recovery of bronchial secretions for culture and, possibly, for cytologic examination. Frequent changes in the child's position, deep breathing, and chest physiotherapy may be beneficial. Oxygen therapy is indicated when there is dyspnea or desaturation. Intermittent positive pressure breathing and incentive spirometry have been recommended when atelectasis is unchanged.

In some conditions, such as asthma, bronchodilator and corticosteroid treatment may accelerate atelectasis clearance. Recombinant human DNase (rhDNase), which is approved only for the treatment of cystic fibrosis, has been proposed for patients without cystic fibrosis but with persistent atelectasis. This product reduces the viscosity of purulent bronchial debris. In patients with acute severe asthma, diffuse airway plugging with thick viscous secretions frequently occurs, with the resulting atelectasis often refractory to conventional therapy. rhDNase has been used in both nebulized form for nonintubated patients with acute asthma as well as intratracheally for atelectasis in intubated asthmatics, with resolution of atelectasis unresponsive to

conventional asthma therapies.

Lobar atelectasis in cystic fibrosis is discussed in Chapter 393 .

Atelectasis can occur in patients with neuromuscular diseases. These patients tend to have ineffective cough and difficulty expelling respiratory tract secretions, which leads to pneumonia and atelectasis. Several devices are available to assist these patients including intermittent positive pressure breathing, In-Exsufflator, and noninvasive bilevel positive pressure ventilation via nasal mask or full face mask. Patients with neuromuscular disease who have undergone surgery are at substantial risk of postoperative atelectasis and subsequent pneumonia. Migrating atelectasis in the newborn infant is a rare and unique presentation and may be secondary to neuromuscular disease.

There is an association between the development of lobar collapse and the requirement for mechanical ventilation. Although lobar collapse is rarely a cause of long-term morbidity, its occurrence may necessitate the prolongation of mechanical ventilation or reintubation. In patients who are ventilated, positive end expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) is generally indicated.

Chapter 401 - Pulmonary Tumors

Susanna A. McColley
Paul R. Haut

Primary tumors of the lung are extremely rare in children and adolescents. An accurate estimate of frequency is difficult because the literature is limited primarily to case reports, and there is a high incidence of “inflammatory pseudotumors.” Metastatic lesions are the most common forms of pulmonary malignancy in children; primary processes include Wilms' tumor, osteogenic sarcoma, soft tissue sarcoma, and hepatoblastoma (see Part 21). Bronchial adenoma and carcinoid are the most common primary tumors. Adenocarcinoma and undifferentiated histology are the most common pathologic findings in primary lung cancer; pulmonary blastoma is rarer and frequently occurs in the setting of cystic lung disease.

Pulmonary tumors may present as fever, hemoptysis, wheezing, cough, pleural effusion, chest pain, dyspnea, recurrent or persistent pneumonia, or atelectasis. Patients with symptoms or with radiographic or other laboratory findings suggesting pulmonary malignancy should be evaluated carefully for a tumor at another site before surgical excision is carried out. Isolated primary lesions and isolated metastatic lesions discovered long after the primary tumor has been removed are best treated by excision. The prognosis varies and depends on the type of tumor involved.

PULMONARY HEMANGIOMATOSIS

In this rare and ultimately fatal disease, uncontrolled vascular proliferation causes progressive dyspnea and eventually leads to death from massive hemoptysis or pulmonary hypertension. Its cause is unknown, although infection may have a role. The vascular abnormality involves the smallest (capillary size) vessels in some patients and slightly larger vessels in others. The pathologic angiogenic process may also extend into other intrathoracic tissues (e.g., mediastinum, pericardium, thymus) or the spleen. Patients usually present with hemoptysis or with right-sided heart failure secondary to pulmonary hypertension. Routine chest films are often similar to those seen in interstitial lung disease. The diagnosis is made by pulmonary angiography (which helps to preclude other forms of veno-occlusive disease) and open lung biopsy. The disease can be locally invasive but is not known to metastasize. The primary process appears to be angiogenesis. Most patients die within 1–5 yr from the onset of symptoms.

A substantial and sustained clinical improvement in a 12-yr-old boy treated with recombinant interferon-a-2a has been reported. Although some hemoptysis was still present, the patient tolerated the treatment well and was clinically stable 14 mo later.

Chapter 402 - Pleurisy

Glenna B. Winnie

The most common cause of pleural effusion in children is bacterial pneumonia (see Chapter 389); heart failure, rheumatologic causes, and metastatic intrathoracic malignancy are the next most common causes. A variety of other diseases account for the remaining cases, including tuberculosis, lupus erythematosus, aspiration pneumonitis, uremia, pancreatitis, subdiaphragmatic abscess, and rheumatoid arthritis. Males and females are affected equally.

Inflammatory processes in the pleura are usually divided into three types: dry or plastic, serofibrinous or serosanguineous, and purulent pleurisy or empyema.

402.1 Dry or Plastic Pleurisy

Dry or plastic pleurisy may be associated with acute bacterial pulmonary infections or may develop during the course of an acute upper respiratory tract illness. The condition is also associated with tuberculosis and connective tissue diseases such as rheumatic fever.

Pathology.

The process is usually limited to the visceral pleura, with small amounts of yellow serous fluid and adhesions between the pleural surfaces. In tuberculosis, the adhesions develop rapidly and the pleura is often thickened. Occasionally, fibrin deposition and adhesions may be severe enough to produce a fibrothorax that markedly inhibits the excursions of the lung.

Clinical Manifestations.

Signs and symptoms are often overshadowed by the primary disease. The principal symptom is pain, which is exaggerated by deep breathing, coughing, and straining. Occasionally, pleural pain is described as a dull ache, which

is less likely to vary with breathing. The pain is often localized over the chest wall and is referred to the shoulder or the back. Pain with breathing is responsible for grunting and guarding of respirations, and the child often lies on the affected side in an attempt to decrease respiratory excursions. Early in the illness, a leathery, rough, inspiratory and expiratory friction rub may be audible, but this usually disappears rapidly. Occasionally, increased dullness on percussion and decreased breath sounds are heard if the layer of exudate is thick. Pleurisy may also be asymptomatic and detected only on radiographs, showing a diffuse haziness at the pleural surface or a dense, sharply demarcated shadow. The latter finding may be indistinguishable from small amounts of pleural exudate. Chronic pleurisy is occasionally encountered with conditions such as atelectasis, pulmonary abscess, connective tissue diseases, and tuberculosis.

Differential Diagnosis.

Plastic pleurisy must be distinguished from other diseases, such as epidemic pleurodynia, trauma to the rib cage (particularly fracture of a rib), lesions of the dorsal root ganglia, tumors of the spinal cord, herpes zoster, gallbladder disease, and trichinosis. Even if evidence of pleural fluid is not found on physical or radiographic examination, a pleural tap in suspected cases often results in the recovery of a small amount of exudate, which, when cultured, usually reveals the underlying bacterial cause in patients with an acute pneumonia. Patients with pleurisy and pneumonia should always be screened for tuberculosis.

Treatment.

Therapy should be aimed at the underlying disease. When pneumonia is present, neither immobilization of the chest with adhesive plaster nor therapy with drugs capable of suppressing the cough reflex is indicated. If pneumonia is not present or is under good therapeutic control, strapping of the chest to restrict expansion may afford relief from pain. Analgesia with nonsteroidal anti-inflammatory agents may be helpful.

402.2 Serofibrinous Pleurisy

Serofibrinous pleurisy is most commonly associated with infections of the lung or with inflammatory conditions of the abdomen or mediastinum. Less commonly, it is found with connective tissue diseases such as lupus erythematosus, periarteritis, or rheumatic fever. On occasion, it is seen with primary or metastatic neoplasms of the lung, pleura, or mediastinum; tumors are commonly associated with a hemorrhagic pleurisy.

Clinical Manifestations.

Because serofibrinous pleurisy is often preceded by the plastic type, the early signs and symptoms may be those of plastic pleurisy. As fluid accumulates, pleuritic pain may disappear and the patient may become asymptomatic if the effusion remains

small, or there may be only signs and symptoms of the underlying disease. Large fluid collections may produce cough, dyspnea, retractions, tachypnea, orthopnea, or cyanosis. Physical findings depend to some degree on the amount of effusion. Dullness to flatness may be found on percussion. There is a decrease or absence of breath sounds, a diminution in tactile fremitus, a shift of the mediastinum away from the affected side, and occasionally fullness of the intercostal spaces. If the fluid is not loculated, these signs may shift with changes in position. In infants, the physical signs are less definite. Instead of decreased or absent breath sounds, bronchial breathing may be heard. If extensive pneumonia is present, crackles and rhonchi may also be audible. Friction rubs are usually detected only during the early or late plastic stage. The process is usually unilateral.

Radiographic examination shows a more or less homogeneous density obliterating the normal markings of the underlying lung. Small effusions may cause obliteration of only the costophrenic or cardiophrenic angles or a widening of the interlobar septa. Examinations should be performed with the patient in the supine and upright positions to demonstrate a shift of the effusion with a change in position; the decubitus position may also be helpful. Ultrasonographic examinations are useful.

Differential Diagnosis.

Thoracentesis should be performed when pleural fluid is present or is suggested, unless the effusion is small and the patient has a classic lobar pneumococcal pneumonia. Examination of fluid is essential to identify acute bacterial infections, and it may disclose tubercle bacilli. Thoracentesis can differentiate serofibrinous pleurisy, empyema, hydrothorax, hemothorax, and chylothorax. In hydrothorax, the fluid has a specific gravity less than 1.015, and evaluation reveals only a few mesothelial cells rather than leukocytes. Chylothorax and hemothorax usually have fluid with a distinctive appearance; differentiating serofibrinous from purulent pleurisy is impossible without microscopic examination of the fluid. The fluid of serofibrinous pleurisy is clear or slightly cloudy and contains relatively few leukocytes and, occasionally, some erythrocytes. Cytologic examination may reveal malignant cells. Protein levels greater than 3?g/dL indicate an exudate and are likely to be associated with an infectious process. Similarly, pleural fluid lactic dehydrogenase values higher than 200?IU/L suggest an exudate. Serofibrinous fluid may rapidly become purulent. A pH less than 7.20 suggests an exudate.

Course.

Unless the fluid becomes purulent, it usually disappears relatively rapidly, particularly with appropriate treatment of bacterial pneumonia. It persists somewhat longer with tuberculosis and connective tissue diseases and may recur or remain for a long time with neoplasms. As the effusion is absorbed, adhesions often develop between the two layers of the pleura, but little or no functional impairment usually results. Pleural thickening may develop and is occasionally mistaken for small quantities of fluid or for persistent pulmonary infiltrates. Pleural thickening may persist for months, but the process usually disappears, leaving no residua.

Treatment.

Therapy should address the underlying disease, although with large effusions, draining the fluid makes the patient more comfortable. When a diagnostic thoracentesis is performed, as much fluid as possible, up to about 1?L, should be removed for therapeutic purposes. Rapid removal of 1?L or more of pleural fluid occasionally has been associated with the ensuing development of re-expansion pulmonary edema. If the underlying disease is adequately treated, further drainage is usually unnecessary, but if sufficient fluid reaccumulates to cause respiratory embarrassment, repeated thoracentesis or chest tube drainage should be performed. In older children with parapneumonic effusion, tube thoracostomy is considered necessary if the pleural fluid pH is less than 7.20 or the pleural fluid glucose level is less than 50?mg/dL. If the fluid is clearly purulent, tube drainage is usually indicated. Systemic acidosis reduces the usefulness of pleural fluid pH measurements. Patients with pleural effusions may need analgesia, particularly after thoracentesis or insertion of a chest tube. Those with acute pneumonia often need supplemental oxygen in addition to specific antibiotic treatment.

402.3 Purulent Pleurisy (Empyema)

An accumulation of pus in the pleural spaces is most often associated with pneumonia due to *Streptococcus pneumoniae*, although *Staphylococcus aureus* is most common in developing nations and in post-traumatic empyema. The relative incidence of *Haemophilus influenzae* empyema has decreased since the introduction of Hib vaccination. Group A *Streptococcus,* gram-negative organisms, tuberculosis, fungi, and malignancy are less common causes. Empyema is most frequently encountered in infants and preschool children. It occurs in 5–10% of children with bacterial pneumonia. The disease may also be produced by

---

rupture of a lung abscess into the pleural space, by contamination introduced from trauma or thoracic surgery or, rarely, by mediastinitis or the extension of intra-abdominal abscesses.

Pathology.

Most commonly, purulent pleurisy is an extensive process consisting of a series of loculated areas involving a large portion of one or both pleural cavities. Thickening of the parietal pleura occurs. If the pus is not drained, it may dissect through the pleura into lung parenchyma, producing bronchopleural fistulas and pyopneumothorax, or into the abdominal cavity. Rarely, the pus may dissect through the chest wall (i.e., *empyema necessitatis*). Pockets of loculated pus may eventually develop into thick-walled abscess cavities or, as the exudate organizes, the lung may collapse and become surrounded by a thick, inelastic envelope (i.e., peel).

Clinical Manifestations and Diagnosis.

The initial signs and symptoms are primarily those of bacterial pneumonia. Children treated inadequately or with inappropriate antibiotic agents may have an interval of a few days between the clinical pneumonia phase and the evidence of empyema. Most patients are febrile. In infants, there may be only a moderate exacerbation of

respiratory distress. The older child is likely to appear more ill and have greater respiratory difficulty. Physical and radiographic findings may be identical to those described for serofibrinous pleurisy, and the two conditions are differentiated only by thoracentesis, which should always be performed when empyema is suspected. Radiographically, finding no shift of fluid with a change of position indicates a loculated empyema; this may be confirmed by ultrasonography or CT scan. The maximal amount of pus obtainable should be withdrawn by thoracentesis. The appearance of pus produced by different organisms is not distinctive; cultures must always be obtained, and Gram-stained smears should be examined for the presence of microorganisms. Blood cultures have a high yield (62% in one series), but latex agglutination may also be useful. Leukocytosis and an elevated sedimentation rate may be found.

Complications.

With staphylococcal infections, bronchopleural fistulas and pyopneumothorax commonly develop. Other local complications include purulent pericarditis, pulmonary abscesses, peritonitis secondary to rupture through the diaphragm, and osteomyelitis of the ribs. Septic complications such as meningitis, arthritis, and osteomyelitis may also occur. With staphylococcal empyema, septicemia occurs infrequently; it is often encountered in *H. influenzae* and pneumococcal infections.

Treatment.

If pus is obtained by thoracentesis, closed drainage should be instituted immediately and controlled by an underwater seal or continuous suction. A catheter with the largest possible internal diameter should be inserted into the site where an accumulation of pus is suspected; sometimes several tubes are required to drain loculated areas. Closed drainage is usually continued for about 1 wk, even though small amounts of material continue to drain after this time, probably in response to the presence of the tube in the pleural cavity. Chest tubes that are no longer draining should be removed.

Instillation of fibrinolytic agents into the pleural cavity to promote drainage may be beneficial, but controlled studies are needed. Antibiotics should not be instilled into the pleural cavity because they do not improve results obtained with systemic antibiotic therapy alone and are associated with local reactions. Controlling empyema by multiple aspirations of the pleural cavity rather than by closed continuous drainage should not be attempted. If the condition is diagnosed early, thoracentesis and antibiotic treatment alone can bring about complete cure.

Systemic antibiotic therapy is required; the selection of the antibiotic should be based on the in vitro sensitivities of the responsible organism. See Chapter 166 , Chapter 167 , and Chapter 178 for treatment of infections by *Staphlococcus, Streptococcus pneumoniae,* and *H. influenzae*, respectively. With staphylococcal infections, resolution of the process is very slow, and systemic antibiotic therapy is required for 3–4 wk. Clinical response in nonstaphylococcal empyema is also slow, even with optimal treatment; little improvement may occur for as long as 2 wk. In patients with inadequately treated empyema, extensive fibrinous changes may take place over the surface of the collapsed lungs, but surgical decortication procedures are rarely indicated. In the child who remains febrile and dyspneic longer than 72?hr after initiation of therapy with intravenous antibiotics and thoracostomy tube drainage, surgical decortication via video-assisted thoracoscopic surgery or open thoracotomy may speed recovery but remains highly controversial. If pneumatoceles form, no attempt should be made to treat them surgically or by aspiration, unless they reach sufficient size to cause respiratory embarrassment or become secondarily infected. The long-term clinical prognosis for adequately treated empyema is excellent, and follow-up pulmonary function studies suggest that residual restrictive disease is uncommon, with or without surgical intervention.

Chapter 403 - Pneumothorax

Glenna B. Winnie

Pneumothorax is the accumulation of extrapulmonary air within the chest. It is uncommon during childhood. Most often, pneumothorax results from leakage of air from within the lung. Air leaks can be primary or secondary and can be spontaneous, traumatic, iatrogenic, or catamenial. Pneumothorax in the neonatal period is also discussed in Chapter 90.8 .

Epidemiology and Etiology.

A primary spontaneous pneumothorax occurs in someone without trauma or underlying lung disease. Spontaneous pneumothorax with or without exertion (Valsalva) occurs occasionally in teenagers and young adults, most frequently in males who are tall and thin. Families have been described in which many members have had spontaneous pneumothoraces, with the onset ranging from birth to adulthood. Patients with collagen synthesis defects such as Ehlers-Danlos disease and Marfan syndrome are unusually prone to the development of pneumothorax.

A pneumothorax arising as a complication of an underlying lung disorder, but without trauma, is a secondary spontaneous pneumothorax. Pneumothorax may occur in pneumonia, usually in connection with empyema; it may also be secondary to pulmonary abscess, gangrene, infarct, rupture of a cyst or an emphysematous bleb (e.g., in asthma), or foreign bodies in the lung. In infant staphylococcal pneumonia, the incidence of pneumothorax is relatively high. It is found in about 5%

of hospitalized asthmatic children and usually resolves without treatment. Pneumothorax is a serious complication in cystic fibrosis (CF) (see Chapter 393), occurring in 10–25% of patients older than 10 yr. Pneumothorax also occurs in patients with lymphoma or other malignancies.

External chest or abdominal blunt or penetrating trauma can tear a bronchus or abdominal viscus, with leakage of air into the pleural space.

Iatrogenic pneumothorax can complicate tracheotomy, subclavian line placement, thoracentesis, transbronchial biopsy, or other diagnostic or therapeutic procedures. Pneumothorax may also occur after acupuncture treatment.

Catamenial pneumothorax, an unusual condition that is by definition associated with menses, results from passage of intra-abdominal air through diaphragmatic defects. When thoracotomy is performed for recurrent pneumothorax of unknown cause in a young woman, an examination of the diaphragm may be appropriate.

Pneumothorax may be associated with a serous effusion (i.e., hydropneumothorax) or a purulent effusion (i.e., pyopneumothorax). Bilateral pneumothorax is rare beyond the neonatal period but has been reported after lung transplantation and with *Mycoplasma pneumoniae* infection.

Clinical Manifestations and Diagnosis.

The onset is usually abrupt, and the severity of symptoms depends on the extent of the lung collapse and on the amount of pre-existing lung disease. Pneumothorax may cause pain, dyspnea, and cyanosis. In infancy, symptoms and physical signs may be difficult to recognize. Moderate pneumothorax may cause little displacement of the intrathoracic organs and few or no symptoms. The severity of pain usually does not directly reflect the extent of the collapse.

Usually, there is respiratory distress, retractions, and markedly decreased breath sounds over the involved lung. The percussion note over the involved area is tympanitic. The larynx, trachea, and heart may be shifted toward the unaffected side. When fluid is present, there is usually a sharply limited area of tympany above a level of flatness to percussion. The presence of amphoric breathing or, when fluid is present in the pleural cavity, of gurgling sounds synchronous with respirations suggests an open fistula connecting with air-containing tissues. Confirmatory evidence is provided when the pneumothorax fills rapidly after it has been aspirated.

The diagnosis can usually be established by radiographic examination. In conditions such as CF, in which the lung is relatively noncompliant, a great deal of air can accumulate under tension without much lung collapse. The amount of air outside the lung also varies with time. A radiograph taken early shows less lung collapse than one taken later if the leak continues. Expiratory views accentuate the contrast between lung markings and the clear area of the pneumothorax. When considering the possibility of diaphragmatic hernia, a small amount of barium may be necessary to demonstrate that it is not free air but is a portion of the gastrointestinal tract that is in the thoracic cavity.

It is important to determine whether the pneumothorax is under tension (i.e., tension pneumothorax) because this condition limits expansion of the contralateral lung and may compromise venous return. It may be difficult to determine if a pneumothorax is under tension. Evidence of tension includes shift of mediastinal structures away from the side of air leak. A shift may be absent in situations in which the other hemithorax resists the shift, such as in the case of bilateral pneumothorax. When the lungs are both stiff, the unaffected lung may not collapse easily and shift may not occur. On occasion, the diagnosis of tension pneumothorax is made only on the basis of

evidence of circulatory compromise or on hearing a “hiss” of rapid exit of air under tension with the insertion of the thoracostomy tube.

Differential Diagnosis.

Pneumothorax must be differentiated from localized or generalized emphysema, an extensive emphysematous bleb, large pulmonary cavities or other cystic formations, diaphragmatic hernia, compensatory overexpansion with contralateral atelectasis, and gaseous distention of the stomach. In most cases, a chest radiograph differentiates among these conditions.

Treatment.

Therapy varies with the extent of the collapse and the nature and severity of the underlying disease. A small or even moderate-sized pneumothorax in an otherwise normal child may resolve without specific treatment, usually within about 1 wk. A small (<5%) pneumothorax complicating asthma may also resolve spontaneously. Administering 100% oxygen may hasten resolution by increasing the nitrogen pressure gradient between the pleural air and the blood. Patients with chronic hypoxemia should be monitored closely during the administration of supplemental oxygen. Pleural pain deserves analgesic treatment. Codeine may be justified, but its respiratory depressant effect should be considered. Occasionally, morphine or meperidine is needed. If there is more than 5% collapse or if the pneumothorax is recurrent or under tension, definitive treatment is necessary. Pneumothoraces complicating CF frequently recur, and definitive treatment may be justified with the first episode, even with less than 5% collapse (see Chapter 393). Similarly, if pneumothorax complicating malignancy and its treatment does not improve rapidly with observation, chemical pleurodesis or open thoracotomy is often necessary.

Closed thoracotomy (i.e., simple insertion of a chest tube) and drainage of the trapped air through a catheter, the external opening of which is kept in a dependent position under water, is adequate to re-expand the lung in most patients. When there have been previous pneumothoraces, it may be indicated to induce the formation of strong adhesions between the lung and chest wall by a sclerosing procedure to prevent recurrence. This can be carried out by the introduction of tetracycline, talc, or silver nitrate into the pleural space (i.e., *chemical pleurodesis*). Open thoracotomy through a limited incision, with plication of blebs, closure of fistula, stripping of the pleura (usually in the apical lung where the surgeon has direct vision), and basilar pleural abrasion is also an effective treatment for recurring pneumothorax. Stripping and abrading the pleura leaves raw, inflamed surfaces that heal with sealing adhesions. Postoperative pain is comparable to chemical pleurodesis with silver nitrate, but the chest tube can usually be removed within 24–48?hr, compared with the usual 72-hr minimum for closed thoracotomy and pleurodesis. The thoracoscope has permitted a successful surgical approach to blebectomy, pleural stripping, pleural brushing, and instillation of sclerosing agents with somewhat less morbidity than occurs with traditional open thoracotomy.

Extensive pleural adhesions help to prevent recurrent pneumothorax, but they also make thoracic surgery, including lung transplantation, difficult. For conditions in which lung transplantation may be a future consideration (e.g., CF), a stepwise approach to treatment of pneumothorax has been proposed. If the patient is comfortable and the pneumothorax is small, no intervention is warranted. For a larger leak or one that does not resolve, simple thoracostomy tube drainage can be attempted. For continuing leak, or recurrence, the next step could be thoracoscopic blebectomy without pleural abrasion. Only after these steps have failed should the full aggressive pleural stripping and abrasion be undertaken. At any step during this approach, the patient and family should be given the option of the definitive procedure if they understand this may make lung transplantation difficult or impossible. It should also be kept in mind that the longer a chest tube is in place, the greater the chance of pulmonary deterioration, particularly in a patient with CF, in whom strong coughing, deep breathing, and postural drainage

are important. These are all difficult to accomplish with a chest tube in place.

Treatment of the underlying pulmonary disease should begin on admission and should be continued throughout the course of treatment directed at the air leak.

Chapter 404 - Pneumomediastinum

Glenna B. Winnie

Pneumomediastinum usually results from alveolar rupture during acute or chronic pulmonary disease. However, a diverse group of nonrespiratory entities can also cause pneumomediastinum; in some of these, the lung is not the source of the air. For example, pneumomediastinum has been reported after dental extractions, normal menses, obstetric delivery, diabetes mellitus with ketoacidosis, acupuncture, and acute gastroenteritis. Pneumomediastinum can also result from esophageal perforation or penetrating chest trauma. Occasionally, no underlying cause is found; in an apparently normal child, the pneumomediastinum can present as chest pain associated with subcutaneous air.

After intrapulmonary alveolar rupture, air can dissect through the perivascular sheaths and other soft tissue planes toward the hilum and enter the mediastinum. Pneumomediastinum is rarely a major problem in older children because the mediastinum can be depressurized by escape of air into the neck or abdomen. In the newborn, however, the rate at which air can leave the mediastinum is limited, and pneumomediastinum can lead to dangerous cardiovascular compromise or pneumothorax (see Chapter 90.8 and Chapter 403). Acute asthma is the most common cause of pneumomediastinum in older children and teenagers. Simultaneous pneumothorax is unusual in these patients.

Clinical Manifestations.

Transient stabbing pains in the chest that may radiate to the neck are the principal features of pneumomediastinum. Isolated abdominal pain and sore throat also occur. The patient may have dyspnea, but it is difficult to know if this is really a separate symptom or if it is related to the chest pain. Pneumomediastinum is difficult to detect by physical examination alone. Subcutaneous emphysema, if present, is diagnostic. Although cardiac dullness to percussion may be decreased, many of these patients' chests are chronically overinflated, and it is unlikely that the clinician can be sure of this finding. A mediastinal “crunch” is occasionally heard but is easily confused with a friction rub. On chest radiography, the cardiac border, highlighted by the mediastinal air, is more distinct than normal and, on the lateral projection, the posterior mediastinal structures are also clearly defined. Subcutaneous air, seen radiographically, confirms the pneumomediastinum.

Treatment.

This is directed primarily at the underlying obstructive pulmonary disease. Analgesics are needed occasionally for chest pain. Rarely, subcutaneous emphysema can cause sufficient tracheal compression to justify tracheotomy; the tracheotomy also decompresses the mediastinum.

Chapter 405 - Hydrothorax

Glenna B. Winnie

In hydrothorax, the fluid is noninflammatory and has a lower specific gravity (<1.015) than that of a serofibrinous exudate. It contains less protein and fewer cells and is usually associated with an accumulation of fluid in other parts of the body, such as the peritoneal cavity and the subcutaneous tissues. Hydrothorax is most often associated with cardiac, renal, or hepatic disease. It may be a manifestation of severe nutritional edema, and it rarely results from venous obstruction by neoplasms, enlarged lymph nodes, or adhesions. It may occur from a ventriculoperitoneal shunt. Hydrothorax is usually bilateral in cases of renal disease or nutritional edema; in myocardial disease, it may be bilateral, limited to the right side, or greater on the right than on the left side. The physical signs are the same as those described for serofibrinous pleurisy (see Chapter 402.2), but in hydrothorax there is more rapid shifting of the level of dullness with changes of position. Treatment is for the primary disorder; aspiration may be necessary when pressure symptoms are notable.

Chapter 406 - Hemothorax

Glenna B. Winnie

Extensive bleeding into the pleural cavity is rare in children but may result from erosion of a blood vessel in association with inflammatory processes such as tuberculosis and empyema. Hemothorax may complicate a variety of congenital anomalies, including sequestration, patent ductus arteriosus, and pulmonary arteriovenous malformation. It is also an occasional manifestation of intrathoracic neoplasms, blood dyscrasias, bleeding diatheses, or thrombolytic therapy. It may be the result of thoracic trauma, including surgical procedures or venous line insertion. Rupture of an aneurysm is unlikely during childhood. Hemothorax also occurs after blunt chest trauma and spontaneously in neonates and older children. A pleural hemorrhage associated with a pneumothorax is called *hemopneumothorax.*

The diagnosis of a hemothorax can be made only by thoracentesis. In every case, an effort must be made to determine and treat the cause. Surgical intervention may be required to control active bleeding, and transfusion is necessary if blood loss

is excessive. Inadequate removal of blood in extensive hemothorax may lead to substantial restrictive disease secondary to organization of fibrin; fibrinolytic therapy or a decortication procedure may then be necessary.

Chapter 407 - Chylothorax

Glenna B. Winnie

Chylothorax results from the escape of chyle from the thoracic duct into the thoracic cavity. The incidence has increased as cardiac surgery is performed on more complex congenital abnormalities; about 50% of these cases are now operative complications resulting from rupture of the thoracic duct. Most of the remainder are associated with chest injury or with primary or metastatic intrathoracic malignancy as a result of the pressure of enlarged lymph nodes or tumor. Less common causes include lymphangiomatosis, restrictive pulmonary diseases, thrombosis of the duct or the subclavian vein, and congenital anomalies of the duct system. Chylothorax can occur in child abuse. In some patients, especially newborns, no specific cause is identified. Chylothorax is rarely bilateral and usually occurs on the left side.

Clinical Manifestations and Diagnosis.

The signs and symptoms relate to the presence of fluid in the thoracic cavity. The diagnosis is established when thoracentesis demonstrates a chylous effusion, a milky fluid containing fat, protein, lymphocytes, and other constituents of chyle. In newborn infants who have not yet been fed, the fluid may be clear. A pseudochylous milky fluid has been reported in cases of serous effusion, in which the fatty material was thought to arise from degenerative changes within the fluid and not from the presence of lymph. This type of fluid may be differentiated from one containing chyle by shaking it with alkalis or ether; the fluid containing chyle tends to become clear. A more definitive test is the quantitation of fluid triglyceride, which is elevated in chylous fluid, and fluid cholesterol, which may be elevated in chronic serous effusions.

Spontaneous recovery has occurred in more than 50% of the reported cases in infants younger than 1 yr of age. Repeated aspirations may be required to relieve the symptoms of pressure. However, chyle reaccumulates quickly, and repeated thoracenteses may cause considerable loss of calories, protein, and lymphocytes. Immunodeficiencies, including hypogammaglobulinemia and abnormal cell-mediated immune responses, have been associated with repeated thoracenteses for chylothorax. Attempts to prevent these problems by intravenous infusion of pleural contents are technically difficult, dangerous, and of doubtful benefit. Despite large losses of T lymphocytes, clinical problems of infection are uncommon, but these patients should be protected from potentially dangerous viruses, including

cytomegalovirus and live virus vaccines.

Treatment.

Therapy should begin in most cases with a brief period of observation on a low-fat (or medium-chain triglyceride), high-protein diet. For most patients, salt restriction and diuresis are also indicated. The total caloric intake should be greater than the average requirement and, several times the daily requirements of the various vitamins, especially the fat-soluble vitamins A and D, should be added. If fluid continues to reaccumulate over 1–2 wk, total parenteral nutrition should be instituted and, if unsuccessful, a more aggressive attempt to locate and ligate the thoracic duct may be indicated. Other therapeutic approaches include pressure control ventilation with positive end-expiratory pressure, inhalation of nitric oxide, subcutaneous octreotide, and pleuroperitoneal shunt placement.

Chapter 408 - Bronchopulmonary Dysplasia

Steven Lestrud

Bronchopulmonary dysplasia (BPD) or *chronic lung disease due to prematurity* is discussed in detail in Chapter 90.3 . This chapter focuses on the course during infancy and childhood.

Clinical Manifestations.

After the neonatal course of RDS and progression of lung disease to Northway stage IV, the clinical features of BPD are varied. Whereas preterm neonates without the diagnosis of BPD may have normal pulmonary function, those requiring supplemental oxygen past 35 wk of postconceptional age have a higher incidence of lower airway obstruction and bronchodilator responsiveness and are more likely to be hospitalized during the toddler years.

Physical findings on pulmonary examination frequently include tachypnea, wheezing, or coarse crackles. Fine crackles may be present in patients prone to fluid overload. The chest wall may have an increased anteroposterior diameter, and intercostal retractions are present. Truncal motor tone is frequently increased, potentially impeding optimum chest excursion.

The most severely affected patients may require prolonged mechanical ventilation to achieve acceptable gas exchange. Infants with significant lung disease will exhibit growth failure owing to elevated energy expenditure essential to maintain increased metabolic demands. Many have baseline hypoxemia, requiring supplemental oxygen to maintain oxygen saturations above 90%; chronic respiratory insufficiency may be evident by elevated bicarbonate levels or elevated Pco_2 on blood gas analysis.

A pulmonary exacerbation is typically triggered during upper respiratory infections. During an exacerbation, the infant will exhibit increased work of breathing, tachypnea and retractions will be evident, and chest wall configuration may change with an increased anteroposterior diameter. If wheezing is a prominent baseline finding, poor air entry during an exacerbation may result in less wheezing.

Patients must be monitored for the development of cor pulmonale, especially if they require supplemental oxygen and have chronic respiratory failure. Other complicating

conditions may include gastroesophageal reflux disease (GERD) and pulmonary aspiration, particularly during an exacerbation when the infants are most tachypneic and when pulmonary mechanics increase risk of GERD. For patients severely affected and those with disease out of proportion to the risk for development of chronic lung disease, other pulmonary disease may be suspected, such as asthma, cystic fibrosis, and chronic aspiration pneumonitis.

Recurrent episodes of respiratory distress may represent anatomic airway abnormalities such as subglottic stenosis and airway malacia.

Treatment.

Treatment is aimed to decrease work of breathing and normalize gas exchange, allowing for optimal growth and neurodevelopment. Adequate caloric intake can be difficult for many reasons, including oral aversion, discoordinate suck and swallow, GERD, aspiration, and aspiration with GERD. In addition, disordered breathing patterns with tachypnea, frequent respiratory distress with increased work of breathing, and requirement for supplement oxygen place the infant at risk for growth failure. A high calorie intake is necessary, with ranges of 120–160?kcal/kg/day required, frequently combined with fluid restriction. To provide such high caloric intake in the compromised neonate, supplemental feedings may be considered through a nasogastric or gastrostomy tube. Careful attention is necessary to maintain fluid balance.

The administration of inhaled glucocorticoids to young children with BPD is considered, owing to the role of inflammation in the pathogenesis of this disease. A frequent finding with BPD is wheezing, particularly with onset of upper respiratory tract infections; however, a severely affected population may have chronic wheeze. The cause of the wheeze may be inflammation, bronchial smooth muscle irritation, bronchial smooth muscle hypertrophy, and airway malacia. As such, the administration of a bronchodilator is frequently undertaken to evaluate an individual's response. ß-Agonists most commonly initially increase air movement and improve comfort of breathing. For patients who respond, the medication should be continued, especially during high-risk periods when triggers are present, such as an upper respiratory infection or hot humid days. Occasionally, ß-agonists will worsen the air exchange; this is characteristic of infants with BPD and concomitant airway malacia. Airway malacia frequently contributes to obstructive lung disease. Bronchial smooth muscle may maintain airway caliber in the malacic airway; smooth muscle relaxation after administration of a ß-agonist results in increased small airway collapse. These patients may benefit from alternative bronchodilators such as ipratropium or methylxanthines.

Gastroesophageal reflux is common and must be suspected in patients not responding to therapy and in patients with frequent exacerbations especially without clear triggers. Definitive diagnosis is necessary because these patients will be subject to prolonged promotility and antacid medications (see Chapter 304 and Chapter 387). Appropriate antireflux therapy in infants with GERD often greatly decreases respiratory complications. Gastroesophageal reflux with pulmonary aspiration or aspiration alone may present as chronic chest congestion, wheezing, and episodic hypoxic spells. Fundoplication with a gastrostomy tube is performed in patients unresponsive to medical therapy. Evaluation and treatment by a speech therapist, pediatric pulmonologist, or otolaryngologist may be necessary to decrease the risk of developing chronic lung disease associated with aspiration.

Attention must be given to prevention of respiratory viral illness. Simple measures should be encouraged, such as frequent handwashing, especially before handling the baby, and avoidance of contact with children and adults with current respiratory symptoms. Sinusitis and otitis media are frequent bacterial infections that result in an exacerbation, particularly in infants with nasogastric tubes or using nasal cannula oxygen. RSV immunoprophylaxis should be considered based on the severity of lung disease, gestational age, and current age.

In general, the *prognosis* for infants with BPD is good. Through school age, the family can expect frequent medical interactions for episodes of respiratory distress frequently triggered by simple upper respiratory tract infections and weather changes. Pulmonary function for severely affected patients will remain decreased, and exercise limitation may be present due to dyspnea. The most severely affected patients will benefit from a multidisciplinary team of caregivers, including the pediatrician, pulmonologist, speech therapist, nutritionist, and developmental specialists.

Chapter 409 - Skeletal Diseases Influencing Pulmonary Function

Steven Boas

Chest wall abnormalities can lead to restrictive pulmonary disease, impaired respiratory muscle strength, and decreased ventilatory performance in response to physical stress. Common causes of skeletal disorders affecting pulmonary function in children include kyphoscoliosis and pectus excavatum. Rarer causes include rib cage anomalies, congenital syndromes, connective tissue disorders, and neuromuscular disease and are discussed elsewhere.

Pectus Excavatum (Funnel Chest)

Pathogenesis.

Midline narrowing of the thoracic cavity is usually an isolated skeletal abnormality. The cause is unknown. It may be associated with a connective tissue disorder (i.e., Marfan syndrome) or rickets, or it may be acquired.

Clinical Manifestations.

The deformity is present at or shortly after birth but is usually not associated with any symptoms at that time. Over time, decreased exercise tolerance, chest pain, palpitations, recurrent respiratory infections, wheezing, stridor, and cough may be present. Because of the cosmetic nature of this deformity, many children experience significant psychological stress. Physical examination may reveal a narrowed anteroposterior diameter, rounded shoulders, kyphoscoliosis, protuberant abdomen, left shift of the cardiac impulse, and an innocent systolic murmur.

Diagnosis.

Lateral chest radiograms demonstrate the depression. An electrocardiogram may show a right-axis deviation. Mitral valve prolapse, Wolff-Parkinson-White syndrome, bronchial atresia, and bronchomalacia are associated. Results of pulmonary function tests may be normal or may show a restrictive defect, if the pectus deformity is severe. Exercise testing may demonstrate either normal tolerance or limitations from underlying limited habitual activity or cardiopulmonary dysfunction. Lowered ventilatory reserves at peak exercise are common, although the clinical significance of these findings remains unclear.

Treatment.

Corrective surgery is beneficial for individuals with restrictive lung disease. Although surgery itself does not reverse the lung restriction, it may halt the progression of cardiopulmonary compromise. For teenagers with exercise limitations, surgical repair may result in improved exercise tolerance. Normalization of lung perfusion scans and maximal voluntary ventilation have also been seen after surgery. Surgery is often performed for psychological or cosmetic reasons.

Pectus Carinatum and Fissuri Sterni

Pectus carinatum (pigeon breast) is an uncommon sternal deformity (1/7th the frequency of pectus excavatum) in which sternal protrusion occurs with lateral depression of the ribs. Males are affected more often than females. Three distinct subtypes (I, keel chest; II, pouter pigeon breast; III, lateral pectus carinatum) have been described with implications for surgical correction. Mitral valve disease and coarctation of the aorta are associated with this anomaly. Scoliosis may occur in these patients, with a subset of children requiring surgery. Surgery is often performed for cosmetic and psychological reasons.

Fissuri sterni congenital (sternal clefts) is a partial (more common) or total midline split in the sternum. This disorder may occur in isolation or may be associated with other congenital anomalies. Surgery is required early in life before fixation and immobility take place.
